possible terms with impunity. All that seems to be considered essential now is enough open space about the building to give it sufficient light, so that its shape and size are those of a narrow "halo" for the former. The school-house monopolizes two-thirds of the spaces leaving only a tiny plat in front, a narrow strip at the sides and a larger plat behind. The lot is bought to fit the building, and whatever ground happens to be left over is turned into a play-ground. Now, this is all wrong, for the play-ground is as necessary and important a part of a good school as the building. The educational and hygienic value of a play-space is enormous. For ourselves, if we were compelled to choose between a school-house without any play-ground and a play-ground without any school-house, we would prefer the latter. A certain area per child ought to be provided just as much as a certain cubic air-space of house room. At least a fourth, if not a third, of the building fund ought to be spent upon the grounds. A liberal space ought to be roofed with glass so as to be available in wet or stormy weather. But what recognition of its importance do we find? Little or none. Not content with reducing it to a mere border around the building and fag end of the lot, we choose the best part of the ground to put the building on. We have seen a building containing four hundred children and its only play-ground the rear half of the lot, which sloped so abruptly down into a ravine that neither gravel nor sand would lie on its surface. Worse yet, with a positive refinement of idiocy, if the remnant of the lot happens to lie in front of the house it is delicately laid down in turf, planted with ornamental shrubs and decorated with signs, "Keep off the Grass"! which ought to be supplemented by placards, "Go Play in the Gutter"! Grass and geraniums are evidently "of more value than many children."

THE DEPOPULATION OF ONTARIO.

The question that has been troubling the French sociologists for the past few years—the low and decreasing birth-rate in their country—is now also becoming a living one with our neighbors over our northern borders; and it would appear with even greater show of reason. If a birth-rate of only 22 to the 1000 should give concern to the French statesmen and physicians, the still lower one of only 20.7 in the Province of Ontario ought, it would seem, to excite still livelier apprehensions for the future of a country that is thus failing in the very source of power, the production of an active and aggressive population. The problem is made the more serious by the reverse condition existing in the adjoining Province of Quebec, where a very high birth-rate has long existed in what some would claim is in many respects an alien and inferior race. The result is that, as in some parts of New England, the French Canadian is crowding out the Anglo-Saxon in certain regions, and fear is expressed that unless

some reversal of present tendencies occurs, all of Eastern Canada will become thus transformed. The matter has been the subject of extensive discussion by the Canadian press, has been seriously considered in at least one convention of a prominent religious body, and will, it seems probable, give still more disquiet to the minds of Canadian publicists and patriots before any final satisfactory facts or conclusions are developed.

As we have said before in this JOURNAL, the question is more a sociologic than a medical one, and yet it has its medical side, and there are many points of view from which it may be of interest to us as physicians. In Ontario the people are, as in France, moderately prosperous, thrifty and forehanded, and in addition to this they annually lose, as in New England, a considerable proportion of their most virile and energetic element by emigration. These are exactly the conditions that might be supposed to tend to a restriction of the birth-rate; the conditions favoring the existence of an aggressive proletariat are lacking. In Quebec, on the other hand, the latter are directly favored by the influence of the Government and the church, as well as by the racial character and social state of the population, which has not been modified as in France, by military and political changes during the past hundred years. In this province we have still the Frenchman of the seventeenth or eighteenth centuries, but living under vastly more favorable conditions; not the French peasant or citizen of today with his burdens of militarism and his non-prolific tendencies.

It has been often charged, especially by some social alarmists among the clergy and elsewhere, who support themselves by the statements of a few medical writers, that amongst the Protestant population of the eastern border of our continent certain very reprehensible practices are commonly resorted to to check the increase of families, such as actual criminal abortion and other illegitimate methods. That any wholesale charges of this kind are likely to be unjust ought not to require argument. A population losing permanently its more vigorous male population by emigration is likely to have its birth-rate reduced. When the late marriages, and the enforced spinsterhood of an undue proportion of the female population are also considered, the case is rendered still clearer. The French Canadians, on the other hand, emigrate to return or take their women with them, their ideals of living are not so high and they marry early, and are probably not specially influenced by considerations of prudence in such matters, while, as already said, they have the direct encouragement of the provincial government, which, it is stated, offers a bounty for large families, and the active sanction of the church. If other proof were wanting of the more direct dependence of the birth-rate upon social and political conditions than upon racial or physiologic peculiarities, the comparison in this regard between

the Gallic race in Canada and in its native France at the present time would alone be sufficient. There is, it is true, a physiologic side to the question; it is well known that high feeding diminishes reproductive capacity in animals, and it is more than merely probable that the same law applies to the human species. The more luxurious, or even the more comfortable we make a people in their living or diet, the less their fecundity.

There is still another feature of the problem that is worthy of attention in a medical point of view. A high birth-rate generally implies also an augmented death-rate, especially in the earlier periods of life. This is seen in the slums of our cities, and everywhere by the general practitioner, who finds the greatest infant mortality in the class that is most productive in this respect. Were this not the case, the question of population would be a more serious one than it is at present, but the fact implies a great waste of human life. It has been calculated that if only one woman in six should do what she was well able to in the way of producing children, the population of the earth could be easily maintained. The rest is a simple arithmetical problem—if four, five or six women out of the six are to do likewise, nature must interfere with some provision to keep down population, and this is generally effected to a large extent by increased infant mortality. At the present time France, with the lowest birth-rate in Europe, has also the smallest death-rate while in some parts of Russia exactly the reverse conditions prevail.

The low Ontario birth-rate, however we may view it, is nevertheless a misfortune to Canada, the greater since, unlike the somewhat similar state of affairs in some of the New England States, the country as a whole does not profit by her emigrants. They come over the border very largely, to add to the wealth and population of the United States, and Canada is the loser. In any way it can be considered, it is a matter worthy of the close attention of Canadian statesmen and patriots.

CEREBRAL TETANUS.

Tetanus has always been regarded as a nervous disease, but it is only since the discovery of the tetanus toxin that one could say precisely that the disease is due to a poisoning of certain nervous cells. The affinity between nervous cells and tetanic toxin is shown very well in the following experiment of KNORR, inspired by WASSERMANN and TAKAKI.¹ The cerebral substance of a guinea-pig is emulsified and mixed with tetanus toxin, and this mixture is then centrifugalized. Two layers form: at the bottom, the nervous matter; above this an opaque fluid. In well-made mixtures it will be found that the fluid thus separated does not contain any poison, which has been fixed to the nervous tissue after the manner

¹ München. med. Wochenschrift, 1898, No. 12.

of a coloring matter. This tangible reaction which occurs in the test-tube also occurs in the organism. The tetanus toxin injected subcutaneously in an extremity of a guinea-pig becomes fixed by the cells of the spinal cord after a certain time, when characteristic contractions appear, part of the poison reaching the cord by way of the nerves, another part by way of the circulating blood.

This specific affinity of nervous elements for the toxin is also shown when one injects the toxin into the brain of a rabbit. In this way is produced a characteristic disease, namely, cerebral tetanus, which has recently been studied by ROUX and BORREL.² This fact alone overthrows the opinion of WASSERMANN,³ that there exists an antitoxin in the normal brain. The poison adheres so strongly to the nervous material with which it is mechanically mixed, that when introduced into the subcutaneous tissue of animals it is not diffused, but is taken up and digested by phagocytes.

The immediate fixation of tetanus toxin by nerve-cells renders it possible to limit the action of the toxin to certain groups of cells. Thus when toxin is injected into the brain of the rabbit or the guinea-pig, there develops as shown by ROUX and BORREL, a disease characterized by intermittent convulsions, motor paralysis and polyuria, together with characteristic psychic disturbances. The injection of five times as much sterilized water or physiologic salt solution in the same manner as a small amount of toxin does not produce any symptoms, hence the results can not be ascribed to mechanic injury.

Eight to twelve hours after the injection the animal becomes restless, turns its head from side to side, runs around in the cage. Abundant urine is secreted; epileptiform convulsions come on, either simultaneously or on slight excitation. The animal grinds its teeth and the wires of the cage; at the same time the hind legs may become paretic. Intermissions in these symptoms often occur. One-tenth c.c. may kill the animal in from twelve to twenty hours; smaller doses give rise to an affection lasting from three to eight or more days; still smaller doses of toxin cause a tetanic affection, with emaciation, from which recovery may take place. It is possible to inject the toxin into various parts of the brain with marked differences in the symptoms produced, and thus there is furnished a novel method of studying the functions of the various regions of the brain that may be of interest from a physiologic standpoint.

The rabbit is much more resistant to tetanus toxin when it is introduced under the skin into the blood than when it is introduced into the brain. The guinea-pig resists the intracerebral injection somewhat better than the rabbit, but the cerebral tetanus of the guinea-pig is as characteristic as that of the

rabbit. In the rat the symptoms of cerebral tetanus are markedly psychic. The animal appears to be subjected to sudden attacks of great fear, and frequently it acts as though it were under the influence of certain delusions or hallucinations.

An animal which receives antitetanic serum acquires a so-called passive immunity and withstands many times the fatal dose of tetanus. ROUX and BORREL made the following experiments: They injected large doses of antitetanic serum subcutaneously into rabbits. Twenty-four hours afterward .1 c.c. of tetanic toxin was injected into the brain, and all the animals died with typic cerebral symptoms in from forty-eight hours to six days later. And yet the blood of these animals contained antitoxins. One drop of the blood of an immunized rabbit mixed with the tetanus poison rendered the mixture inoffensive, when introduced into the brain of a new rabbit. The extravasation of a small amount of blood during the intracerebral injections of immunized animals may neutralize the toxin and prevent the appearance of cerebral tetanus. In guinea-pigs, therefore, similar experiments often failed to produce the desired result, because their brain is more vascular than that of the rabbit and less susceptible to the tetanus toxin.

All these facts can also be demonstrated to be true as to the diphtheria toxin, which is more rapidly fatal when inserted into the brain than under the skin. Immunized animals resisting enormous doses of toxin given subcutaneously perish when a small quantity is introduced into the brain. The symptoms are more exclusively nervous, and at the autopsy one does not find any of the characteristic lesions of diphtheria intoxication, as for instance, congestion of the suprarenal capsules, because all the other organs have been protected by the antitoxin except the nerve-cells. Hence it is very evident that the nerve-cells have not the same affinity by any means for the antitoxin as for the toxin. This is probably the reason why, in the prevention of tetanus, antitoxin serum so often fails, because when the antitoxin is used a part of the toxin has already become fixed to the nerve-cells. The antitoxin may neutralize the poison which is still circulating, but does not reach that which is fixed by the cells of the brain or spinal cord.

Further experiments by ROUX and BORREL show that a few drops of antitetanic serum injected into the brain have a much better effect in tetanus of animals than large quantities of antitoxin introduced into the blood or under the skin. Intracerebral injection does not save all the tetanized animals. It must be injected before a certain length of time has elapsed after the poisoning. Before recommending this method of administering antitoxin in human tetanus ROUX and BORREL insist that it will be necessary to extend the experiments to various species of animals, because it may be that in the horse and sheep, for instance, as well as in man, the results

² Annales de l'Institut Pasteur, 1898, No. 4.

³ Berlin klin. Wochenschrift, 1898, No. 1.

would be different from those observed in guinea-pigs and rabbits.

As already stated, rabbits and guinea-pigs passively immunized suffer from cerebral tetanus when the toxin is injected into the brain. The question arises: Is this also the case in animals whose immunity is active? This question is very pertinent, because many observers have advanced the opinion that antitoxin is elaborated by the cells which are susceptible to the toxin; that each symptom which is influenced by the toxin responds by producing antitoxin. Two rabbits immunized against tetanus, and possessing an antitoxic serum, were found to be insusceptible to subcutaneous injection of 12 c.c. of tetanus toxin, which was fatal in a dose of 2 c.c. in the case of a susceptible rabbit. One-tenth c.c. of toxin was introduced into the brain of the immune rabbits at the same time as into a normal control animal. On the following day all the rabbits presented signs of cerebral tetanus. The control animal died during the course of the day; the immunized animals died with typic symptoms, one after seventeen days, the other after twenty days. These experiments demonstrate that the nerve-cells of an actively immune rabbit are sensitive to the toxin and that it becomes very difficult to understand how these nerve-cells could prepare an antitoxin. It would appear, on the other hand, as if during the course of the immunization the nerve-cells had never come into contact with the toxin.

Certain animals are naturally immune to various microbic toxins. The rat, for instance, does not suffer from a dose of diphtheria poison which is sufficient to kill several rabbits. One-tenth c.c. of diphtheria toxin was injected into the brain substance of a rat, and death followed on the third day, hence the brain of the rat is also sensitive to the poison, and as it does not die when large quantities of toxin are injected subcutaneously, it follows that the poison does not then reach the brain but is arrested in some part of the body. The natural immunity of the rat does not depend upon the resistance of the nerve-cells against diphtheria, but upon some other property of the body. ROUX and BORREL showed that similar facts obtained with regard to the rabbit as to morphin, toward which this animal is looked upon as being insusceptible. In other words, the nerve-cells of the rabbit are not insensitive to morphin.

All the facts go to show that in acquired as well as in natural immunity against certain poisons, the immunity does not depend upon insusceptibility of the nerve-cells, at least not of those of the brain. The poisons are retained by other cells, which exercise a protective rôle and probably manufacture antitoxins. ROUX and BORREL ask: Where are those cells? and answer that perhaps phagocytic cells are capable of also destroying the poisons produced by microbes. They are not ready to insist upon this, but it would seem to them that the questions of immunity against the microbes and of immunity against the toxins will ultimately receive similar solutions.

CREOSOTE NOT A SPECIFIC.

The drug, creosote, has become so inseparably connected in history, in clinical experience, and in present day teachings, with the disease of pulmonary tuberculosis, that its acceptance as a specific becomes a natural consequence. Such empiricism, however, is fatal to the scientific treatment of tuberculosis even though creosote does seem to be indicated in every case. Creosote probably exercises its curative action in the lung because of its physiologic property of stimulating the bronchial mucosa, where it is eliminated, and its action as an expectorant; not as a specific for the disease of tuberculosis.

The healthy human body is not susceptible to infection by the germs of tuberculosis because a vital resistance of the tissues prevents the development of any bacteria that may gain entrance, and those bacteria that develop in a lung to cause a miliary tuberculosis, do so because—from malnutrition, lack of exercise, the inhalation of sewer gas or dust particles, an ordinary cold or a previous attack of pneumonia—the lung tissues possess a diminished resistance and afford a suitable soil for their development. A diminished resistance is probably present in the bronchial mucosa, of which there is a vast expanse in the lung, and when an infection is once established at a given point it is clear that the adjacent mucosa will afford slight hindrance to an extension of the tubercular process. The object of our treatment should be to raise the vital resistance of these adjacent cells of the bronchial mucosa, in order that they may resist an extension of the disease and thus limit the tubercular inflammation to a single spot, which should mean an eradication of the disease. Creosote *does* improve the resisting power of each cell, because it stimulates it to a more perfect metabolism, and if to this favorable condition there are added an abundance of good food to supply these cells with nourishment, and plenty of fresh air to supply the blood with good red oxyhemoglobin that may further assist their metabolic processes, the patient is placed under the best conditions for recovery. The creosote, it will be observed, does not exercise an antibacillary action, nor does it even diminish the virulence of the tubercle bacillus, but as a treatment for tuberculosis it is the most satisfactory agent that we know, since it succeeds in establishing a condition of health in the mucosa that will help nature to overcome the disease.

CORRESPONDENCE.

The Jugglery of Statistics. A Reply to an Absurd Editorial.

WASHINGTON, D. C., Oct. 22, 1898.

To the Editor:—I desire to invite attention to the editorial comment in the *Philadelphia Medical Journal* of Oct. 15, 1898, under the caption: "The One Fact the Whitewashing Committee Must Explain." I would not have troubled you with this communication but that I have regarded the said

journal as a paper of value and of increasing importance whose editorial utterances should have weight. The article to which I take exception as unworthy of the columns in which it appeared, presents to its readers the large ratio of deaths from disease in the Spanish War, as the one fact to be explained, "the crux of the entire discussion," and manifestly elated with his discovery, the editorial writer exclaims in a burst of triumph: "Explain us that right thoroughly and without equivocation, Honorable Sirs," etc. This exuberance of diction from the editorial pen manifests that the writer sent his manuscript to the printer while dazzled by the brilliance of his discovery and without giving it that careful consideration which is needful for the reputation of the editorial columns. I am constrained to look upon this as the explanation of the article. Doctors are generally credited with being weak on figures, and my experience shows that they are not strong in questions of ratios, making honorable exception in this regard of the health officers who deal systematically with medical statistics. I must charitably suppose that the writer in question participates in the general professional failing because I am unwilling to believe that he knowingly presented figures which did not sustain his conclusions, trusting that the latter would be accepted by readers who were unfamiliar with his arithmetical premises. These premises are that: There were killed in the War of the Rebellion 46,874, died of wounds 39,715, died of disease 172,907; and in the recent war: killed 289, died of wounds 65 and died of disease 2565. These figures are official, and I have no exception to take to them. But he continues: "If we reduce these figures to percentages based on the best estimates of the numbers of soldiers participating, and place figures side by side we find:

"Causes of Deaths.	Civil War.	Spanish War.
Killed	18.1%	9.6%
Died of Wounds	15.3%	2.3%
Died of Disease	66.6%	88.1%."

Now in the calculation of these ratios no consideration is given, as claimed by the editorial, to "the best estimates of soldiers participating" nor, I may add, to the relative duration of the two wars. They express merely the relative proportion of deaths from battle casualties and disease in the constitution of the total mortality. Yet from these data the editorial writer, knowingly or unknowingly, concludes that the 88.1 per cent. of deaths from disease in the Spanish War, as compared with the 66.6 per cent. in the Civil War is a point of the highest importance. "There can be no possible question" he says "that the general mortality from disease has been greatly and indubitably lessened in the last thirty-three years. If so, of course the percentage mortality from disease in the Spanish War should be decidedly lower than in the war of the Rebellion. Instead of this it has been decidedly higher," and the members of the Presidential Investigating Commission are called upon to take note that the medical profession regards the cause of this as the main thing that is before them for explanation.

The absurdity of this may be well illustrated by adding to the statistics and ratios given above those derived from the reports of the engagement of Admiral Dewey's fleet on May 1, 1898, at Manila. Dewey's fight lasted only one day. The figures given for the Spanish War covered a period of five months and those for the Civil War a period of five years and two months; but as the element of time does not enter into the calculations of the ratios criticised this element need not be considered in the engagement at Manila. Here we find that no man was killed, no man died of wounds received, but that one man, an engineer officer, succumbed to heat exhaustion or insolation. Stating these figures as percentages of the total mortality we find: killed 0 per cent. died of wounds 0 per cent, died of disease 100 per cent, as compared with 88.1 per cent. in the Spanish War and with 66.6 per cent. in the War of the

Rebellion. If it is needful for the Honorable Sirs to give such high consideration to the greater death-rate from disease as compared with the deaths from wounds and deaths on the battle-field in the Spanish War considered as a whole, how serious is the consideration they ought to give to this frightful rate of mortality from disease as compared with that from battle casualties in the Bay of Manila.

It was my intention in beginning this letter to state the conclusions that are really admissible from the figures and ratios presented by the *Philadelphian Medical Journal*, but the pressure of current work at this time is very great, and I conceive that I have effected my purpose by directing attention to the unsubstantial basis on which the argument of the editorial writer was constructed.

Respectfully yours,
CHAS. SMART,
Deputy Surgeon-General, U. S. Army.

Twins with Complications.

LAUREL, IOWA, Oct. 18, 1898.

To the Editor:—October 2 I was called to attend Mrs. R. in confinement and found myself confronted with a number of unpleasant conditions, not the least of which was a morbid fear on my patient's part that she would not be able to give birth to her child, or children as proved to be the case, she having been told at her previous confinement, about a year ago, when she gave birth to triplets, all still-born, that she would not live through another confinement. She was a German woman, large and strongly built, about 40 years of age and had given birth to five children, the oldest 14 years of age. She said she had suffered a great deal at all her previous confinements and that they had been slow, lasting from twenty-four to forty-eight hours. She complained of being "deathly sick" and felt as if she was going to vomit.

From the size and shape of the abdomen, I concluded I had a case of multiple pregnancy, but the sound of but one fetal heart could be heard on auscultation. Digital examination revealed an irregularly contracted vagina, due, no doubt, to the healing of her previous lacerations. The os, however, was fully dilated, and I found a foot protruding, which as a strong pain now came on, I grasped, making slight traction and with some manipulation succeeded in bringing down the other foot. During the next pain the body was born and the head, with chin to the front, was engaged in the superior strait. Now, when good pains were most needed, the patient "gave up" and wished me to leave her to die, as she had been told that she must. Finally, after a delay (which proved fatal to the child) she was delivered of a large girl weighing eight pounds. Another child could be outlined high up in the fundus uteri, and digital examination showed a "cone-shaped" bag of water through the os. The fetal parts could not be made out. The patient gave up entirely, and I let her rest an hour and a half, when, as the pains did not come on, I gave her 15 m. fl. ext. ergot and in a short time they again became quite strong and regular. Another digital examination showed that the child was not presenting, hindered, I think by the low attachment of the placenta. But by making slight downward pressure from above during a pain, I finally succeeded in getting the parts to engage. The sac, which was very dense, had to be ruptured, when an unusually large amount of the liquor amnii came away and I found a foot protruding almost exactly as did the first one. The child, a boy, also weighed eight pounds and was alive, but minus the penis. Where the penis should have been there was a slight elevation about one-eighth of an inch above the surface, with an opening at the apex, through which the child urinates. The placenta, which was delivered in about thirty minutes, also seemed to share in the general anomalous condition. It consisted of two distinct placentæ, seemingly enveloped in a common sac. They were connected at their sides by a strong fibrous band and each had

a circulation of its own, there being no anastomosis of blood-vessels between them. I report this case because of its many bad features and of its comparatively happy ending, as at this writing the mother and baby are doing well. I hope it may be of interest to at least some of the readers of the JOURNAL, who, like myself, have not practiced long enough to become familiar with this class of cases and patients.

Respectfully

L. W. PENCE, M.D.

ASSOCIATION NEWS.

To Commemorate Joseph O'Dwyer's Name—At the meeting of the Section on Diseases of Children of the AMERICAN MEDICAL ASSOCIATION held at Denver, Colo., June 7-10, 1898, it was moved and carried unanimously that a Memorial Committee be appointed to commemorate the late Joseph O'Dwyer, with suitable powers, etc., to collect such moneys and to act with other bodies for the same purpose. The committee is composed of the following: Dr. Louis Fischer, New York, chairman; Dr. J. P. Crozer Griffith, Philadelphia, and Dr. F. E. Waxham, Chicago.

SOCIETY NEWS.

Tri-State Medical Association.—The Tri-State Medical Association of Mississippi, Arkansas and Tennessee, meets in Memphis, Dec. 20-22, 1898. Physicians attending this meeting are promised a pleasant and profitable time in the "Queen City of the Mississippi Valley." Titles of papers should be sent to Dr. Richmond McKinney, secretary, Continental Building, Memphis, Tenn.

Utah State Medical Society.—At the recent meeting of this Society the following were chosen officers for the ensuing year: President, C. M. Wilson of Park City; vice-president, Ira A. E. Lyons of Salt Lake; second vice-president, J. W. Aird of Heber City; secretary, R. W. Fisher of Salt Lake; treasurer, E. S. Wright of Salt Lake; board of censors, G. M. Perkins of Ogden, W. W. Betts of Salt Lake, G. L. Smart of Springville, H. J. Powers of Ogden, A. J. Hosmer of Salt Lake.

Cumberland County (N. J.) Medical Society.—This society held its semi annual meeting at Hotel Cumberland, October 11, with the president, Dr. A. Judson of Newport, in the chair. A paper on "Peritonitis" was read by Dr. Hummel of Deerfield. Dr. Charles P. Noble of Philadelphia read a very interesting and instructive paper on "Conservatism in Gynecology." The society unanimously voted to celebrate its eightieth anniversary on Dec. 8, 1898.

Mississippi Valley Medical Association.—The following officers were elected at the recent meeting: President, Duncan Eve, Nashville, Tenn.; first vice-president, A. J. Ochener, Chicago; second vice-president, J. C. Morfit, St. Louis; secretary, Henry E. Tuley, Louisville, Ky. (111 W. Ky. St.); treasurer, Dudley S. Reynolds, Louisville; chairman of committee of arrangements, Harold N. Moyer, Chicago. Chicago was selected as the next place of meeting, in October, 1899, the date to be determined by the executive officers and the chairman of the committee of arrangements.

Washington, D. C., Medical Society.—At the meeting of the 19th inst. Dr. Sterling Ruffin presented the specimen and gave the history of a very interesting case of aneurysm of the aorta, which involved the entire arch, but did not give the symptoms of pulsation during life; the other usual symptoms, however, were well marked, the patient eventually dying of inanition. The subject was discussed by Dr. Claytor, who referred to the latest points of diagnosis, calling especial attention to the frequent mistake of considering the preystolic murmur associated with that form of aneurysm as being of valvular heart

origin, and the subsequent injudicious treatment with digitalis. He referred to similar cases occurring in his own practice. Dr. Storch read an essay entitled "Function of the Appendix Vermiformis." The principal function which he assigned for this organ was that of a lubricant to the caput coli. He considered constipation, and not obstruction by intestinal contents, the cause of appendicitis; he considered the appendix a necessary organ and its function an important one. Dr. D. S. Lamb did not agree with Dr. Storch, but believed the appendix had no physiologic function. He regarded the organ as a degeneration of a formerly existing diverticulum from the intestines, and being a degeneration was prone to disease. He considered the only function the organ possessed was that of inducing disease and death. He went into the morphology of the appendix, calling attention to its existence in certain animals and absence in others, and explained the evolution, anatomically, which appeared to explain its origin. The discussion was continued in a very interesting and instructive way by Drs. A. F. A. King, Stone and J. Ford Thompson.

Detroit Academy of Medicine.—The annual meeting of the Detroit Academy of Medicine was held October 13, and the following officers elected for the current year: President, F. W. Robbins; vice-president, Geo. Duffield; secretary and treasurer, H. D. Jenks; trustee, J. E. Emerson. Reports from retiring officials showed the society to be in a flourishing condition. The annual address was given by the retiring president, Dr. David Inglis, on "Social Factors of Today and the Future of the Medical Profession." He said that for weal or woe the steady trend of modern life is toward socialism. Socialism as distinguished from individualism has already affected the medical profession in the matter of the license to practice being restricted to qualified practitioners. There can be no doubt that all thoughtful medical men favor State examining and licensing boards. Michigan is an unfortunate example of pure individualism in this matter. Socialism, as exemplified in the change from competition to combination, is at the bottom of the steady extension of hospitals, dispensaries, railway and other contract surgeons and physicians. Like the trust and department store, these phases of combination are probably permanent. Socialism as exemplified in the concentration of wealth seriously affects medical incomes. If, as the *Iron Age* puts it, "Prosperity has returned, but it is prosperity based on a permanently lowered rate of wages," medical incomes must also be permanently lowered. Finally, as it seems likely that the way out of combination of capital for private gain will be found in the combination of capital for the public weal, the full establishment of a commonwealth, so medical men will find under the socialism so evolved an opportunity to pursue scientific medicine unhampered by the present overpowering commercialism. After the regular meeting Dr. and Mrs. Inglis entertained the members and their wives.

NEW INSTRUMENTS.

A SCIENTIFIC OZONE INHALER.

BY CYRUS EDSON, M.D.
NEW YORK CITY.

In describing this new instrument, which I have devised for the purpose set forth in the foregoing title, the adjective "scientific" has been used in order to distinguish the apparatus from the numerous so-called "ozone inhalers" with which physicians and the laity are confronted in advertising columns and on every hand—nostrums which develop so little ozone that chemic means have never been able to detect it. In point of fact, the word "ozone" has been so abused by misuse in connection with inhalers that it has come to mean something physicians view askance. This ozone inhaler was suggested to me by a conversation with a medical friend who told me of a

series of cases of phthisis pulmonalis treated by him that were greatly benefited by inhalations of ozonized air. These patients had been made to inhale the air acted on by the discharge between the poles of a static machine.

The familiarity of physicians with the properties of ozone makes it quite unnecessary for me to enter upon a dissertation respecting the antiseptic and disinfectant qualities of ozone. It may be well, however, to point out the fact that the beneficial effect of climatic change to regions abounding in pine forests in cases of respiratory diseases due to germ infection, is generally ascribed to the presence of ozone in the air of such localities in greater amount than elsewhere.

The ozone inhaler is well shown in the accompanying cut. Two terminals or poles (A A) are passed into a glass receiver, about a foot wide in its greatest diameter, through holes bored in the glass for this purpose. These poles are so constructed

as to be separated or approximated at the will of the operator and are connected with the poles of a static machine by means of insulated wire, just as the Crooke's tube for X-ray work is connected. One wire carries the current from the positive and the other from the negative pole of the machine. An apparatus capable of throwing at least a six-inch spark is best adapted for the purpose. The glass receiver has two large openings, one of which is terminated in a mouthpiece (B), while the other is connected by means of rubber tubing (C) with an air-tank containing air under pressure. The rubber tubing is furnished with a stopcock (D) for the purpose of regulating the supply of air. The inhaler may, however, be used without this air-supply. When used with it, the stream of air enters the apparatus in such a way as to pass directly between the poles or terminals inside the receiver, and thence on through the mouthpiece, to be breathed by the patient. When in operation,

the current is seen passing through the space between the two terminals in the form of a silent discharge spray or a stream of sparks, depending on the separation or approximation of the poles. The amount of ozone developed is directly under control of the operator. The silent discharge when the poles are widely separated effects the development of the maximum amount of ozone, while the amount lessens as the poles are approximated. The ozone admixture may be further controlled by regulating the air supply from the air-tank to the receiver. The amount taken by the patient may be still further graduated by having him inhale the stream of ozonized air as it issues from the mouthpiece, his face being at a greater or less distance from it, or by having him apply his lips to the mouthpiece, thereby drawing the admixture of air and ozone directly into the respiratory tract.

In using ozone as a remedial means in the great quantity capable of being furnished by this apparatus, we must bear in mind that it is an exceedingly powerful and active agent, having stronger affinities than oxygen, rapidly destroying all forms of bacterial life. In comparatively weak admixture with air, it is very irritating, and should be inhaled with caution. The strength of the ozonized air should be carefully regulated to suit each case or violent coughing and strangling will follow its respiration. With a little care, however, commencing with a very weak admixture and increasing its strength gradually until very slight irritation is apparent, then decreasing a little to the point of tolerance, it can be safely administered. Its beneficial effects are almost immediate. Cough and expectoration are rapidly diminished and a marked general improvement follows.

I have noted also that the appetite of persons in health to whom the inhalations were given for experimental purposes, was increased; the action of the heart became stronger; the face flushed, and the effects noted after administration of oxygen were apparent. It is too early yet to report cases upon which this treatment has thus far been tried. Suffice it to say that I have used it both alone and as an adjuvant to other treatment, in a number of cases of phthisis and of bronchial catarrh, and am more than pleased with the results. I hasten to give the ozone inhaler to the profession, well knowing that it will appreciate the device to be valuable, since its operation and application are founded upon sound principles.

Before closing, I would add that I have modified the apparatus so as to apply a similar device to the purpose of furnishing quantities of ozonized air to hospital wards, dwellings, theaters, etc. The object of this is to revivify the atmosphere of such places. I believe it of importance that the air in wards of contagious-disease hospitals be kept fresh by this means. Benefit to the patients suffering from diphtheria and other contagious diseases must necessarily follow, if not directly from remedial effect of ozone operating as a bactericide, at least as a result of improvement of the air-supply furnished for breathing.

As in the case of the inhaler, the ozone admixture can be regulated and supplied in any effective strength, while the cost of application in this electric age will be inconsiderable after the apparatus has been once introduced.

Messrs. Van Houten & Ten Broeck of 300 Fourth Avenue, New York City, have constructed the inhaling apparatus after my designs, and caused the cut shown here to be made.

20 West Forty-eighth Street.

RAMAUGE'S NEW INTESTINAL COUPLER.

A. Ramauge of Buenos Ayres again presents a device for an improved button (*Semana Médica*, September 1). A cylindric tube 2 c.m. long by 1 wide, is finished at each end with a circular rim projecting 1 cm., thus making the total diameter of the button 3 cm. The edge of these rims toward the centre of the tube slopes from the outside in so that the

outer edges of the rims are much nearer together than the part close to the tube, thus forming a couple of partly enclosed canals encircling the tube, while the surface of the tube is left exposed between them. This exposed space is studded with small holes. These partly enclosed canals are packed with compressed sponge forming a couple of sponge rings around the tube held in place by the overarching rim at each end. Some water is then introduced into the two ends of the intestines and a draw-thread run around each edge. The button is then inserted and the threads drawn tight, thus fastening the intestine around the free space in the center of the tube. The water is then made to flow down to the spot and as it finds its way through the small holes the sponge begins to swell and gradually compresses the two ends of the intestine together, above the threads, until they become consolidated in the peripheral line of the serous surfaces in contact, while the central part will slough away and release the button. No actual tests of the button had been made at the time of his communication.

NECROLOGY.

C. S. Arthur, M.D., Portland, Ind., October 17.—John H. Benedict, M.D., Danbury, Conn.—William Bigham, M.D., Seville, Ohio, October 13.—N. T. Bornar, M.D., Gainesville, Texas, October 9.—Henry M. Boyers, M.D., Grafton, W. Va., October 14, aged 27 years.—Samuel Creadrick, M.D., Philadelphia, October 19, aged 57 years.—D. H. Dickinson, M.D., Topeka, Kan., October 18.—Richard Dingee, M.D., Newportville, Pa., Jefferson Medical College, 1860, aged 70 years.—John B. Fares, M.D., Romeo, Mich., Rush Medical College, 1884, October 14, aged 69 years.—Henry Geiger, M.D., University of Heidelberg, 1861, October 15.—Hezekiah Gilbert Leigh, M.D., Petersburg, Va., October 17, aged 65 years.—Charles McCulloch, M.D., Albany, N. Y., 1877, October 15, at Gloversville, N. Y., aged 50 years.—G. W. Mills, M.D., Sedalia, Mo., October 16, aged 46 years.—W. N. Plank, M.D., Deer Creek, Ind., October 11, aged 45 years.—Peter A. Rivard, M.D., Rochester, N. Y., October 19, aged 46 years.—John Garson Stuart, M.D., Fortville, Ind., October 11, aged 73 years.—W. E. Swanston, M.D., Devil's Lake, N. D., October 14.—R. M. Wigginton, M.D., Waukesha, Wis., October 16, aged 60 years.

DEATHS ABROAD.—Max Wiener, professor of obstetrics at Breslau.—Karl von Mettenheimer of Schwerin.

DONALD A. TAYLOR, M.D., acting assistant-surgeon at Fort McPherson, died of peritonitis, October 15, aged 25 years. The Doctor was a graduate of the University of Virginia. At a meeting of the medical staff of the United States General Hospital at Fort McPherson, Ga., held on Oct. 16, 1898, the following resolutions were adopted:

WHEREAS, It has been our sorrow to lose from our midst our friend and colleague, Dr. Donald A. Taylor, Acting Assistant-Surgeon, U. S. A., and,

WHEREAS, His premature death has been in consequence of disease contracted in the faithful performance of his duties,

Resolved, That we, the members of the medical staff of the United States General Hospital, Fort McPherson, Ga., do hereby express our esteem of our late friend and colleague, and our regret for his sudden loss.

Resolved, That a copy of these resolutions be sent to the family of our deceased colleague, in expression of our heartfelt sympathy with them in their bereavement; and further be it

Resolved, That copies of these resolutions be furnished to the following journals for publication: *The Army and Navy Register*, *The Army and Navy Journal*, *The Journal of the American Medical Association*, *The Atlanta Constitution*. [Signed] For the staff:

WALLACE NEFF,
Major and Brigade Surgeon, U. S. V.
CHARLES E. B. FLAGG,
Captain and Assistant-Surgeon, U. S. A.
J. C. GARLINGTON,
Acting Assistant-Surgeon, U. S. A.

PUBLIC HEALTH.

Toxicity of Woman's Milk with Diphtheria.—The *Arch. Clin. de Bordeaux* for August reports a case of severe diphtheria not treated with serum, in which tests of the milk even late into convalescence proved that it was toxic for guinea-pigs, hence would have proved toxic for her infant had she been allowed to nurse it.

Governmental Research on Malaria.—The London *Lancet* announces that a commission for investigating the various questions associated with malaria, which has been appointed by the Colonial Office and the Royal Society, consists of the following members: Dr. C. W. Daniele of British Guiana; Dr. S. R. Christophers of University College, Liverpool; and Dr. J. W. W. Stephens, John Lucas Walker student in Pathology in the University of Cambridge. Drs. Christophers and Stephens will proceed almost immediately to Pavia to work in the laboratory of Professor Golgi and thence to Rome to work in Professor Cetti's laboratory. The Commission will eventually proceed to Africa, when its first work will in all probability be to determine the clinical varieties of malarial fevers occurring there.

Sodium Sulphocarbolate in Scarlet Fever.—J. J. Gonzales describes (*Cronica Médica Mexicana*, October 1), his success in preventing contagion of the other children in a family when one child was infected with scarlet fever during a recent severe epidemic. The isolation was very incomplete, if attempted at all. His dose was 30 cgm. a day for children under 3 years of age; 50 cgm. for children from 3 to 10 and from this to 1 gm. for older persons, administering it for more than a month and thus entirely preventing contagion in seventeen families and a hospital, protecting 139 other children exposed. Two cases of contagion occurred, one showing evidences of the disease a few hours after commencing the sulphocarbolate, and the other having refused to take it at all. It was tolerated perfectly in every case with no after-effects of any kind.

Yellow Fever.—The dispatches since our last report (vide JOURNAL, p. 998), are as follows: October 18, New Orleans, 2 new cases and 1 death; Wilson, 4 new cases; Franklin, 1; Jackson, Miss., 4 and 1 death; Yazoo City, 4; Waveland, 1; Madison, 2; Hattiesburg, 2 and 1 death; Poplarville, 6 new cases; Starkville, 1; Edwards, 5; Natchez, 3; Orwood, 4; Harriston, 2. Frost throughout the fever belt gave promise of a decrease in the fever, but October 19 Jackson reported 6 new cases; Natchez, 4; Madison, 5; Canton, two suspicious cases; Hattiesburg, 2 new cases and 1 death; Oxford, 4 new cases. Quarantine restrictions in Northern Alabama were removed on this date. On October 20, but 1 new case was reported at Jackson, Miss.; 3 and 1 death at Yazoo City; 2 and 1 death at Hattiesburg; 1 at Harriston; 1 death at Warren, Ohio; 3 new cases and 3 deaths at New Orleans. October 22 dispatches reported frosts through the infected districts generally, while quarantine in Mississippi was removed. All traffic restrictions being removed in Louisiana trains began running regularly October 24.

Sero-diagnosis of Leprosy.—Professor Spronck of Utrecht announces that Hansen's bacillus can be cultivated on glycerinated and neutralized potato (10 days, 38 degrees C.) and continues to flourish transferred to Loeffler's gelatinized horse serum or, even better, simple fish bouillon (cod or turbot). Artificial culture produces a modified form of the lepra bacillus, resembling more the diphtheria and pseudo-diphtheria bacilli than the Koch bacillus. It is not pathogenic for animals. It is very seldom that the serum of a non-leprosy person will cause agglutination even at 1 in 30 to 1 in 40, but in every one of the twelve cases of leprosy he examined, agglutination was produced with 1 in 60 to 1 in 1000, except in three cases of anesthetic leprosy dating from fifteen to thirty-two

years, which required 1 in 20 to 1 in 40. The leprous serum will retain its agglutinating power six weeks if 1 per cent. phenicated bouillon is added and air and light kept out. Dried, it retains the agglutinating power a month at least. Living recent cultures must be used for the sero-diagnosis.—*Semaine Méd.*, September 28.

Malt Soup for Infants.—The Breslau University children's clinic has long been investigating to discover a food adapted to cases with gastro-intestinal disease, and reports in the *Deutsche Med. Woch.* of September 28 the extremely satisfactory results attained with a food made of 50 grams wheat flour stirred in one-third of a liter of cow's milk, and worked through a sieve. In another bowl 100 grams malt extract are dissolved in two-thirds of a liter water at 50 degrees C., and to this is added 10 c.c. of an 11 per cent. solution of potassium carbonate. The malt extract mixture is then stirred into the flour-milk and the whole cooked together. A table of the gain in weight in 28 cases is appended (all less than six months old), which averages very high under the circumstances, 43 grams a day in one case, fed on the malt soup 31 days. None of the children had severe rachitis afterward. The article concludes with an appeal for more children's hospitals, as the benefits to infants of scientific treatment and diet far outbalance the burden of the extra responsibility they would entail.

The Plague in Vienna.—The press dispatches of the 23d announce that the plague situation in Vienna continues extremely critical, the death of Dr. Mueller, on this date, adding to the already great alarm that the city will not escape the plague. Dr. Mueller attended Herr Barisch, the surgical assistant at Professor Nothnagle's bacteriologic establishment, who died on Tuesday. Great precautions have been taken to prevent infection from the dead and sick. Dr. Mueller recently returned from Bombay, where he studied the plague and brought with him some of the bacilli. He cultivated the bacilli and Professor Nothnagle and he have been experimenting with them on lower animals with a view to obtaining a serum with which to inoculate against the plague. The man Barisch was a servant in the laboratory, which he kept clean. He also fed the dogs, cats, rabbits, and guinea-pigs on which Professor Nothnagle experimented with the plague bacilli. When Barisch was taken ill he was removed to the Vienna General Hospital, where the physicians, learning his last and dangerous occupation, isolated him. Dr. Mueller then attended Barisch. When Barisch died a bacteriologic examination proved him a victim to the dread disease.

Prevention of Epilepsy.—Children react with convulsions to so many slight causes, gastro-intestinal disorders, fright, etc., that they are always standing on an inclined plane as far as these reflex phenomena are concerned, and each attack progressively increases the danger of epilepsy by lowering the "threshold of the neuron." Max Breitung of Cologne asserts that epilepsy should never be allowed to develop, and that the physician of the future will devote much energy to switching off to another track any child that shows the slightest hereditary or acquired tendency to convulsive attacks. This can be accomplished by wise supervision, dietetic and physical measures and moral training at home and in school, avoiding any disturbance of the nervous system, keeping up the reserve of nerve strength and toning up the neurons so that they will subside rapidly into repose after an excitation. As "dietetics of stimulations," he mentions mild electric baths, massage, tepid douches, etc., and muscular exertion, gardening, carpentering, drawing, book-binding, etc. He refers to the bicycle as a wholesome exercise when rationally used "but who uses it rationally? certainly not the bicyclist-thropos curvatus of the present day!" He adds that this "Bahnungshygiene," as he calls it, is a seed for the future. "It requires time, but the Eden of Humanity, in which, as

gardeners we work, extends timeless before us. Every progress in our science and our art hastens the day when the physician will be the freely chosen guide of mankind."

Not Part of State Quarantine System.—Many complaints are being made concerning the quarantine detention camp at Egmont Key, and almost invariably it is thought that this camp is a part of the Florida quarantine system. This is a mistake, as that camp is a creation of the United States Marine-Hospital Service, is run entirely by the United States Government and is managed and controlled by the Federal authorities. Neither Dr. Porter nor the State Board of Health has anything whatsoever to do with the management of that station. A gross injustice is, therefore, done the State quarantine system and the health officer when the two are confounded. Governor Bloxham has recently been petitioned in respect to the brutal, immoral and indecent environment of that camp, showing that those presenting charges believe it to be a part of the State's health protective system. It is therefore necessary that the attention of the public should be invited to the great distinction between that quarantine camp and the various quarantine stations of our State Board of Health. The Tampa Bay quarantine station, on Mullet Key, is, and has been for eight years, built, operated and controlled by the State Board. The quarantine detention camps at Egmont Key (Tampa Bay) and those near Key West are part of the United States quarantine system, and are entirely separate and distinct from and in no way connected with the State stations.—*Jacksonville Times-Union and Citizen*, October 1.

Sanitary Surgery.—The following appeared as an editorial in the *New York Evening Post* of March 4, 1898:

SANITARY SURGERY.

Attention has recently been called in these columns to the importance of the establishment in the United States of a National health organization, which should be so broad in scope and so wise in detail as to render speedily and practically available to the citizens of the whole country those new measures for the prevention of diseases which science has within the past few years made known. We have deprecated the notion, still prevalent in many minds as a heritage of an earlier day, that quarantine is the be-all and the end-all of national health organizations.

That this suggestion was not premature is attested by the fact now become widely known that the committee of the Senate at Washington, having the matter in charge, has reported favorably, not a bill to create a National health bureau, with all its wide and beneficent possibilities, but a bill to increase the quarantine powers of the Marine-Hospital Service. This bill, known as the Caffery bill or Wyman's bill, gives almost dictatorial powers to the Supervising Surgeon-General of the Marine-Hospital Service in all parts of the country, and, in its recent modifications, sanctions the establishment of a system of annoying espionage upon the State quarantines, largely ignoring the important ends for which a National health bureau is urgently demanded by the medical profession.

This Wyman-Caffery bill seems to have been framed largely from the point of view which dominated the New York quarantine under the redoubtable Jenkins, a few years since, and which was a source of much keen mortification to the medical profession of the country. Apart from the implication which this bill carries, that quarantine is one of the most important functions of a National health organization, its provisions, if legalized, would place grave commercial as well as sanitary interests in the hands of a single individual, who, not inconceivably, might be more a politician than a sanitarian, more concerned in strengthening his service and his following than in fostering conditions of public and private sanitation, which, the world over among civilized people, are tending to reduce quarantine to an entirely subsidiary function.

We do not, of course, in suggesting such a sinister possibility, allude to the present organization of the Marine-Hospital Service. The medical profession is the best judge of the eminence, as a sanitarian, of the present supervising Surgeon-General. They can best judge whether or not his administration has been signalized by absolute devotion to science to the exclusion of all political involvement of the great bureau which he directs. But legislation like this must not be made for a day, but should have in mind all possible personal vicissitudes of administration.

The so-called Spooner bill, now before Congress, providing

for a national health bureau of the wide scope which we have indicated, guards against the abuse of power in quarantine as in other matters of administration, by the creation of an advisory council representing the various parts of the country, which would share with the head of the bureau or commission the responsibilities of critical situations, and secure attention to the often diverse interests of various parts of the land.

It will interest the student of the civilization which this country is evolving, sometimes it seems in very jerky fashion, to see whether the United States, through their representatives at Washington, are to practically ignore the great advance which sanitary science has made within the last two decades, and the high possibilities for the prevention of disease which are close at hand, and revert to such a blind and ignorant reliance as marked the era of sanitary savagery.

MISCELLANY.

An Enormous Brain.—While the average weight of the European brain is 1380 grams, Bismarck's weighed 1867, Cuvier's 1830, Byron's 1807, Kant's 1650, Schiller's 1630 and Dante's 1420. But is weight synonymous with power?

Hernia of the Luog.—There are forty cases on record and Potain adds another, the first observed in the suprasternal region. Tuffier reduced a pneumocele lower down by suturing the pleura in stages, curing the hernia completely, but this would have been impossible in this case, and fortunately the intratracheal tension held it in check.—*Semaine Méd.*, September 28.

Oidomycosis.—The *Vienna klin. Woch.*, of September 29, describes the case of a woman of 64 years with symptoms of acute cystitis and pneumaturia. The urine was found full of thrush flakes, forming a two-inch sediment in a pint glass and quantities still floating. The bladder was washed out twice with a thousandth solution of arg. nitr., which cured the trouble so that the patient did not return. The bacteriologic investigation showed that though the oidomycosis was so pronounced, yet the pneumaturia was due to the presence of the bacillus coli.

Generalised Scleroderma.—The necropsy of a very severe case of this affection showed the nervous system intact, and the arteriosclerosis noted entirely out of proportion to the severity of the cutaneous lesions. The dermatosclerosis was, therefore, a specific lesion, the direct effect of the cause of the disease, which must be some toxic substance affecting the connective tissue, as the toxins of tuberculosis are supposed to produce the "cutaneous tuberculides," according to a current theory. In fact preceding infective diseases have been noted in scleroderma: rheumatism, typhoid fever, erysipelas, diphtheria, etc., and in the above case, syphilis.—*Semaine Méd.*, September 28.

Stimulation before Operation.—Before a major operation, Hanks of New York (*Am. Gyn. and Obstet. Jour.*, September) uses the following method of "moderate and judicious stimulation" in all cases: Commencing six hours before the operation, he administers from one to three teaspoonfuls of good whisky in one ounce of hot water every hour until the time for operation, and two hours before the operation he passes into the rectum, "high above the brim, if possible, from one to two ounces of good whisky in four ounces of warm, normal saline solution, adding, when it may be wise, a little tincture of opium." He believes the patients, so prepared, recover more quickly from the ether narcosis, and generally return to complete consciousness in less than one hour.

Artificial Anus in the Symphysis.—Roux of Lausanne cuts out a U shaped piece of bone in the upper edge of the symphysis without disturbing the rectus muscle, and brings a loop of the intestines through the hole in such a way that the vertical proximal intestine fills the upper four-fifths of the U, while the distal intestine is compressed flat in the lower fifth. The loop is then sutured to the bone below and the rectus muscle above. If a

neoplasm has to be removed, it is inspected at this time, but not removed until later, after the artificial anus is working perfectly. The bony setting for the anus possesses great advantages. The feces are easily discharged, bending forward, the bandages keep their place better and the subject can conceal his condition much more satisfactorily.—*Cbl. f. Chir.*, from *Revue Méd. de la Suisse Romande*, 1898, No. 1.

To Close Defects in the Skull.—Prof. A. Barth recently announced that a successful bony regeneration of a defect was only to be obtained by supplying calcareous salts for a foundation, which is best accomplished by filling the space with a spongy calcined bone, easily prepared and sterilized. He proved his assertions on animals and—in one case of pseudoarthrosis of the tibia—on man. J. Grekoff reports (*Cbl. f. Chir.*, October 1) his success in two children, both extensive defects, one quite ancient. The calcined bone (shoulder-blade of a calf) has healed firmly in place (five to seven months) and percussion elicits the normal sound. He recommends the method in high terms to others, advising filling the defect as smoothly as possible, freshening the edges, absolute asepsis and young subjects. No test has yet been made on an adult.

Laryngeal Diphtheria.—In the *Am. Gyn. and Obstet. Journal* for September, Rosa Engelmann presents an analysis of 100 cases of laryngeal diphtheria. She found that sex played an unimportant rôle, although the 100 cases showed a preponderance of males. Age, she considers a decided factor, and the day on which the antitoxin was given had a more appreciable effect on the cases not intubated than on those intubated. In the former, even as late as the fifth and thirteenth days, "surprisingly good results were obtained."

Heliotherapy Founded by Diogenes.—Sir Samuel Wilkes, in the *Practitioner*, announces himself as a follower of the cynic philosopher, Diogenes. He says: "The remedy for consumption is not medicine, but fresh air. In various parts of the globe this may be obtained. Seeing that all the places best fitted for consumptives are blessed with sunshine, it is quite possible that the latter may be one of the conditions favoring recovery; it may be directly destructive to bacilli, as the warmth and the beauties of the landscape brought out by it indirectly excite the interest of the patient and revivify his nervous system. Air and sunshine are the needs of the consumptive; without them no other remedies will succeed. When reading at school of Diogenes in his tub, and the visit of Alexander the Great to him, I thought he was a man of very bad manners in telling the monarch to get out of his sunshine, and it was not until late years that I took a different estimate of the philosopher. After an attack of influenza I went to Worthing to convalesce, requiring air and sunshine. Everything else was put aside for these; they were my only wants. When, therefore, as I sat looking on the sea and basking in the sun, a friend stopped in front of me to talk, he was stripping me of my only shred of comfort, and I exclaimed, 'Get out of my sunshine.' I then discovered the greatness of Diogenes, who evidently knew that the sun was the source of all power."

Serum Treatment with Serum from Convalescents.—Walger reports four cases of abdominal typhus treated with typhus serum, and with such favorable results that he recommends the method to others. He injected 10 c.c., repeating the injection in one case of relapse. Weisbecker has been very successful in cases of measles, scarlet fever, typhus and pneumonia, with serum from a convalescent, and he now reports equally favorable results in thirty cases of diphtheria. One injection is sufficient—from 4 to 6 or from 8 to 10 c.c., according to the age of the child. The serum must be obtained exclusively from diphtheria patients whose disease healed spontaneously, that is, without any injections. The epidemic of diphtheria was exceptionally severe, but with these single injections the mortality was only 12 to 13 per cent. The gen-

eral health improves at once after the injections, the croupy cough is transformed at once into an ordinary catarrhal cough, and a copious perspiration occurs in nearly every case, followed by a falling temperature.—*Munich Med. Woch.*, September 27.

Optic Neuritis and Brain Tumors.—Krauss (*Phila. Med. Jour.*, October 1), in a study on brain anatomy and brain tumors, concludes that optic neuritis is present in about 90 per cent. of all brain tumors, more often in cerebral than in cerebellar, the location of the tumor exerting little influence over the appearance of the papillitis. Over the production of the papillitis the size and nature of the tumor also has little influence, while slow-growing tumors are less likely than the more rapid to be accompanied with optic neuritis. He believes it "probable that unilateral choked disc is indicative of disease in the hemisphere corresponding to the eye involved," and considers it doubtful whether increased intra-corneal pressure is solely and alone responsible for the production of an optic neuritis in cases of brain tumors.

Stone in the Bladder.—With the belief of many, that recurrence of stone is especially liable to occur after litholapaxy, Cabot (*Boston Med. and Surg. Jour.*, September 29) does not agree. In his experiences, cases of recurrence after litholapaxy have, with one or two exceptions, been due to a general diathesis or local conditions. Recurrence follows the suprapubic operation also, and he concludes from his cases that the constant reappearance of a phosphatic stone in the bladder usually indicates the resistance of some local cause which should be sought and removed." He believes the suprapubic affords the best opportunity for inspection and operative treatment of the condition found. For removal of stone he thinks litholapaxy the safest operation, and usually competent to work a complete cure.

Electricity in Gynecology.—In considering the limited but fairly well-defined field in which electricity may be used, not only with safety but also with advantage, Ford (*Medical News*, October 1) includes the following conditions: amenorrhea in young women, not dependent on their anemia, "but rather in connection with plethora, in which there is an undersized or undeveloped uterus due to perimetritic inflammations, which have resulted in slight bands of adhesions about the broad ligaments; cutting off the blood-supply;" amenorrhea following long, exhausting nervous affections, with or without anemia; simple metritis, where ovaries and tubes are not infected; dysmenorrhea dependent on neuralgic tendency or on slight bands of constriction about the Fallopian tubes, without pus formation; hydrosalpinx; subinvolution dependent on infection after childbirth, when there are no pus collections about the tubes or ovaries, and small fibroids in the uterine wall.

New Electric Lighting Filament.—One of the chief difficulties in electric lighting is to find a filament which will emit the light without being itself consumed. A scientific journal reports the discovery of a new substance which appears to have the qualities desired in greater proportion than any yet used. This is called osmium, the densest and most refractory of all metals, being infusible except at the highest attainable temperature. Osmium is found native as an alloy in certain ores of platinum and iridium. It is a hard, bluish gray metal with an extraordinary atomic weight and enormous specific gravity. It is said to be the heaviest substance known. The properties that suggested its use for incandescent lamps are its practical infusibility, and its known resistance to temperatures in which platinum and iridium volatilize and disappear. It is well known that the intensity of light emitted by an incandescent substance increases rapidly with its absolute temperature. By heating osmium in a vacuum with an electric current strong enough to volatilize platinum, it is said to attain a luminosity hitherto unknown, emitting a white light of an agreeable color, but of great intensity.—*Scientific American*.

Spirilla in Pleuritic Exudation.—In a case of pleurisy treated in the military hospital of Munich, Dr. Welke detected very peculiar micro organisms, which he has described in the *Munich Med. Woch.* A soldier presented symptoms of pleurisy and pneumonia; he suffered from rigors, high fever, pains in the chest, etc.; on percussion there was dullness in the left side; auscultation showed bronchial respiration with rhonchi, and an exploratory puncture gave evidence of highly fetid purulent exudation. Before an operation could be performed a large quantity of this fluid was suddenly discharged through the bronchi, the fever decreased, and the patient recovered, although very slowly. During convalescence, pleurisy of the other side appeared, but passed off in a few days. In the fluid obtained by the puncture, Dr. Welke discovered, in addition to leucocytes and streptococci, a great number of filiform micro-organisms which were extremely motile, displacing the leucocytes in the course of their movements. Some of them had a fusiform process at each end, and their length was from 100 to 140 μ ($\frac{1}{250}$ to $\frac{1}{180}$ in). By and by, their motility became less and stopped altogether in from twenty five to thirty minutes, when the pus had become cold. The fluid discharged through the bronchi could not be examined until after the lapse of two hours, by which time the organisms were, of course, dead. It was not found possible to classify the organisms; their great strength proved that they did not belong to the bacilli, and Professor Hertwig, to whom they were shown, believed them to be either spirilla or protozoa. How they had come into the pleuritic exudation could not be ascertained; probably they had made their way into the pulmonary abscess during the act of inspiration, and finding this medium favorable to their development they had increased very rapidly.—*London Lancet*, September 24.

Rape by Boy Between 7 and 14 Years of Age.—If it be conceded, says the court of appeals of Kentucky, in *Davidson vs. Commonwealth*, Sept. 11, 1898, that the testimony showed that the accused was not 14 years of age, yet clearly showed that he was much more than 7 years old, and that the jury were authorized by the evidence to believe beyond a reasonable doubt that he was physically capable of committing the crime of rape, and that he was mentally capable of understanding that it was wrong to do so, a verdict of the jury finding him guilty of the offense as in this case is sustained by sufficient evidence.

Sufficiently "Visible Mark."—An accident insurance policy contained a provision that it should not cover "any injury, fatal or otherwise, of which there is no visible mark upon the body." The shoulder of the policy holder of the plaintiff in the case of *Thayer vs. the Standard Life & Accident Insurance Company*, was injured by a fall, causing pain, and depriving him of the use of the arm, but the only visible mark of the injury was a discoloration of the arm and shoulder. A point was sought to be made of this. But, in overruling exceptions to a judgment for the plaintiff, the supreme court of New Hampshire holds that the "visible mark upon the body" required by the policy need not be a bruise, contusion, laceration, or broken limb, but may be any visible evidence of an internal strain which may appear within a reasonable time after the injury is received.

Special Physical Examination Indispensable.—Where a civil service regulation requires an application for appointment to a position of a certain class to be accompanied by a certificate of a practising physician of good repute that he has examined the applicant, and found him free from any physical defect, etc., and a further regulation requires that, "whenever physical qualifications are of prime importance to the proper discharge of the duties in any position, applicants must pass an additional examination as to their physical condition and capacity," the second appellate division of the supreme court of New York hold, in *People vs. Gleason*, July 23, 1898, that the examina-

tion required by this second regulation must be had under the direction of the civil service commissioners, and that no other method of examination is a compliance with the rules, and it is immaterial that any other physician's certificate may have been accepted by the board as final, such acceptance being a clear disregard of the civil service regulations.

Why a French Physician was Fined.—A physician in France was recently fined, although not very heavily, for refusing to testify in a matrimonial action to the circumstances of an altercation which he had witnessed between the husband and wife on the occasion of a visit which he made to the family in his professional capacity. The quarrel occurred immediately upon his arrival at the house, and he went away without either prescribing or giving any medical advice whatever. For this reason the divorce court held that he was absolved from all obligations of professional secrecy, and was bound to disclose what he saw, just as any non-professional witness would be. He contended, on the other hand, that inasmuch as he had been summoned solely as a medical adviser, his presence at the scene was wholly due to his professional character, and that if he had not been there as a doctor he would not have been there at all, in which event he would have nothing to tell. The smallness of the fine imposed, which was only 10 francs, indicates that the court did not deem his refusal to testify a very heinous offense, and before he was compelled to give the desired evidence the case was settled.—*New York Sun*.

"Deferred Annuities" for Medical Men.—Annuities, so popular among the professions in Great Britain and the Continent of Europe, do not find much favor on this side of the water. In addition to this being the case as to regular annuities, whereby a certain sum is paid down in cash for an annuity to commence its year at once, "deferred annuities" are rarely if ever heard of in America, although they have been adopted to a great extent in Europe and are readily obtainable from life companies here. A "deferred annuity" is one under the condition of which the yearly payment commences early in life, and the annuity does not go into effect until, say, ten, twenty or thirty years have elapsed. The American companies, however, make very little mention of them in their circulars and manuals, and therefore even a well-informed agent connected with one of our life companies may be excused for not being informed on the subject.

The "Camp Ghost" at Camp Wikoff.—The following sketch of the physical human wrecks that were so numerous at the Montauk recuperation camp appeared in a New York Journal: "The most pitiable sight that is to be seen at camp, outside of the hospitals, is the 'ghost' type. The 'camp ghost' is the man who is not ill enough to be admitted to the hospital, but is too weak to do duty. He has nothing to do but wander, and he really lacks the strength for this, but he always essays it, with the result that he drops by the wayside and lies until a jolting army wagon or hospital conveyance picks him up. Or, feeling his energy waning, he essays a short cut over the succession of ground swells that exist here. There was one of the Twenty-Second Regulars whose knees gave out when he was in the hollow between the hillocks one morning. On his hands and knees he crawled through a marsh to the summit of the neighboring hillock and there fainted. Swirling banks of fog were chasing each other over the land, limiting the range of vision to a few yards all the morning, and it was not until noon that two volunteers found him and carried him to the roadway. 'Such cases,' says one of the surgeons here, 'are just about beyond treatment. I have not yet been able to comprehend the condition of mind and body which produces the 'camp ghost.' The cause is the hardships of the Cuban campaign, repeated attacks of fever, and lack of nourishing food at the time when it was most needed. Yet these ghosts are not ill in the ordinary meaning of the term. There is no specific ailment. They

are simply devitalized. It is useless to take them into the hospitals. Their best chance is in plenty of fresh air and cheering companionship, although there is little enough of the latter. If we could surround those fellows with the people they love and who love them, we could guarantee 99 per cent. of cures. It would revive their interest in life. As it is, their sad faces are a contagion. They droop a little more each day, until one day they droop into the hospital. The next day they are more than likely to be dead. On the records we put it down as exhaustion, and I guess that is pretty near it; exhaustion of all the vitalizing instincts that bind a man to this earth'."

Temple of Esculapius.—The German archeologists working in Greece have excavated the celebrated Temple of Esculapius on the Island of Paros, described by several Greek authors. It measures 41.25 by 19.5 meters, and is in an excellent state of preservation, though pillaged of all its treasures.

Personal.—Dr. F. E. Waxham of Denver, Colo., has returned to Chicago, with office in the Columbus Memorial building and residence at 3633 Grand Boulevard.

New Publication.—The *Texas Clinic*, Vol. i, No. 1, October, 1898, comes to our exchange table. It is to be published monthly at \$1.00 a year, and is edited by J. B. Shelmire, M.D., Dallas, Texas.

Societies.

The following recent meetings are noted:

Illinois.—Esculapian Society of the Wabash Valley, Paris, October 27; Brainard District Medical Society, Petersburg, October 27; Chicago Gynecological Society, October 21; Military Tract Medical Association, Canton, October 20; Scandinavian Medical Society, Chicago, October 21; Stephenson County Medical Society, Freeport, October 13; Will County Medical Society, Peoria, October 25.

Maryland.—Johns Hopkins Medical Society, Baltimore, October 17.

Michigan.—Saginaw County Medical Society, Saginaw, October 14.

Missouri.—Medical Society of City Hospital Alumni, St. Louis, October 20; St. Louis Medical Society of Missouri, October 22.

New Hampshire.—N. H. Surgical Club and Center District Medical Society, joint session, Concord, October 11.

New Jersey.—Camden District Medical Society, October 11.

New York.—Central New York Medical Association, Auburn, October 18; Jefferson County Medical Society, Syracuse, October 11; Oneida County Medical Society, Rome, October 11; Washington County Medical Society, Whitehall, October 6.

Pennsylvania.—Franklin County Medical Society, Chambersburg, October 18; Lycoming County Medical Society, Williamsport, October 14.

Vermont.—State Medical Society, Brattleboro, October 13 and 14; Vermont Sanitary Association, Montpelier, October 25.

Wisconsin.—Kenosha County Medical Society, October 13; Northwestern Wisconsin Medical Association and Fox River Valley Medical Society, joint session, Oshkosh, October 25.

Cincinnati.

APPOINTMENT.—Dr. Louis Molony has been appointed acting assistant-surgeon in the volunteer army to be stationed in Santiago with Brigade-Surgeon Lawrence Carr of this city.

DR. WALLACE NEFF, Brigade-Surgeon U. S. V., has been visited with a severe attack of appendicitis, at his station near Atlanta, Ga. He was attended by Dr. C. A. L. Reed of this city.

OHIO VOLUNTEERS.—The surgeons of the First Ohio Volunteers are busy examining the members of the regiment previous to their mustering out. The soldier makes a written statement of his condition which he signs, answering as to whether he has any physical disabilities, and if so, when, where and how he received them. This is followed, if the man declares that he has any such disability, by the certificate of the company's commander. The man is then examined and the surgeon makes his written report as to the man's condition. Major Hendley is in charge of the examining.

SOCIETY FOR ORIGINAL RESEARCH.—At the regular meeting, October 13, Dr. J. E. Greive presented specimens of the various forms of syphilis of the brain and spinal cord.

Baltimore.

MEDICAL SCHOOLS.—The winter sessions of the schools are now in full swing. The University of Maryland and College of Physicians and Surgeons are recovering from the effects of the adoption of the four-year course in 1895, and have increased classes, especially the former. The University is much advanced by the splendid new hospital and its successful school for nurses. Professor Tiffany, who, owing to some disagreement with his colleagues of the faculty, had withdrawn from didactic teaching, has resumed full charge of the chair of surgery. Prof. Hammett has one of the finest clinical laboratories in the country, and gastric physiology, pathology and therapeutics are demonstrated there in all the fullness of their modern development. There was no formal opening at the University. Prof. Bevan opened the course at the College of Physicians and Surgeons, Prof. Street at the Baltimore Medical, and Prof. Batchelor at the Woman's Medical. I understand the class at the Baltimore Medical is smaller than usual, owing to the four-year rule coming into operation there for the first time with the class of 1896. What is to be the status of our new college, "The Maryland Medical," is only a matter of conjecture. It opened in September with twenty-five to thirty students. It has a three-year course, but the sessions are of eight months. The Baltimore University has a supplementary session each year in the spring months. Really the number of schools has multiplied so here that the question of a name is becoming a difficulty, almost all the available terms being already appropriated. We have now here seven "regular" schools, including one for women, one homeopathic school, three dental schools and one college of pharmacy.

OPENING ADDRESS.—The medical event of the week has been the address of Prof. T. Clifford Albutt, of Cambridge University, at the opening of the Johns Hopkins. Prof. A. is returning home from the Pacific Coast, where he has been delivering a series of lectures. The address was largely technical. There were many non-medicals in the audience, including ladies. The Johns Hopkins opened with 207 students, a larger number than ever before. This is the seventh session. There were no graduates until the fifth session, no students being admitted to advanced standing. There are now thirty-five women in attendance, nine being new students. The first year class numbers sixty-six. The new buildings of the medical school are approaching completion and will be occupied during the present session. The hospital occupies four squares, but the college buildings occupy another entire square. Prof. Osler has been quite ill since his return from Scotland, where he went to receive the degree of LL.D. He has been suffering from influenza which led to pneumonia. He has, however, recovered sufficiently to leave the city and is now recuperating in the mountains of Pennsylvania. He expects to return and assume the duties of his chair and deanship on November 1.

CENTENNIAL.—We are looking forward to a great occasion next year when we will celebrate the centennial of our Medical and Chirurgical Faculty. One hundred years ago the society was chartered by the Legislature of the State and given control of professional interests in Maryland. One hundred and one physicians, representing all the counties of the State, were named as incorporators in the charter. Organization was effected at Annapolis, June 2, 1799, the first president being Dr. Upton Scott of Annapolis, an Irish physician who came over with Governor Sharpe in 1753. Prof. Samuel C. Chew holds the office this year, having been selected as above all others in the State fitted to fill the chair during the centennial year by reason of his high standing, his ripe scholarship and his dignity. The semi annual meeting of the faculty will be held next month in Frederick City, Md. Through the generosity of the Messrs. Frick the medical library has made great strides the past two years and now has a really fine collection of books available. It is especially rich in those departments in which Prof. Charles Frick was interested—fevers, renal, nervous and intestinal diseases.

Washington.

ST. ELIZABETH'S HOSPITAL.—The report of Dr. W. W. Godding, the surgeon-in-chief of the Government Hospital for the Insane, for the year ended June 30, 1898, shows there were 1767 patients at the close of the last fiscal year; 437 were admitted during the present year, making a total of 2204 patients treated; of this number 351 were discharged, 93 recovered, 49

improved, 3 were not insane, and 197 died. The general summary shows that 32.28 recovered, 16.26 improved, 2.39 were unimproved, and 31.87 died. Since the opening in 1855, 10,772 cases have been treated, of which number 3478 recovered, 1749 improved, 3433 died, and 2726 were unimproved. The daily average of inmates during the present year was 1798, an increase of 88 over the preceding year. He asks for additional space and an increase of appropriation to care for the large number of patients, which have come to the hospital as a result of the Spanish-American war, and recommends a change in the existing laws governing the commitment of the insane patients. As a result of an increase of 20 per cent of patients during the past year, he asks for deficiency appropriation of \$12,000 in order to settle last year's accounts.

MICROSCOPIC SOCIETY.—At a recent meeting the following officers were elected: President, Dr. H. H. Robbins; vice-president, Prof. Hall Bartsch; corresponding secretary, H. H. Doubleday; recording secretary, L. M. Mores; treasurer, Dr. Robert Reyburn; curator, W. H. Seaman. A committee was appointed to draft suitable resolutions on the death of Dr. Edwin A. Gibbs, a member of the Society.

CLINIC PATHOLOGICAL SOCIETY.—At the meeting of the society, on the 18th inst., the following officers were elected: President, Dr. John Van Rensselaer; vice-presidents, Drs. John R. Wellington and Sterling Ruffin; recording secretary R. T. Holden; corresponding secretary, J. T. Kelly; treasurer Frank Leach.

HEALTH OF THE DISTRICT.—The report of Health Officer Woodward for the week ended October 15, shows the total number of deaths to have been 100, of which number 60 were white and 40 colored. At the close of the week there were 131 cases of diphtheria and 90 of scarlet fever under treatment. The annual death-rate for the whites was 16.29, and for the colored 23.43. There were 5 fatal cases of typhoid fever, 6 of diphtheria and 1 of scarlet fever. There were 125 births, of which 99 were white and 26 colored. Dr. A. Barnes Hope has been appointed a physician to the poor, to act during the illness of Dr. William G. Morgan.

EPISCOPAL HOSPITAL.—At the recent quarterly meeting of the Eye, Ear and Throat Hospital, it was announced that Bishop Satterlee had set aside the last Sunday in October as hospital Sunday, and that all collections on that day, in the local churches would be donated to the hospital fund; the Directors are endeavoring to secure an endowment of \$50,000. The total number of patients treated during the past nine months, ended September 30, was 1027, 553 white and 474 colored. One hundred and thirty-six patients have been received into the Hospital; 173 operations have been performed; \$998 has been received for pay patients.

UNLICENSED DENTISTS FINED.—A Dr. Crosby, who was tried and convicted on the charge of violating the law regulating the practice of dentistry, by engaging in practice without a license, was fined \$50 by the judge of the police court. The local dentists are highly gratified by the enforcement of the law. So far, they have been much more successful in enforcing their Act than the doctors have in enforcing their regulation.

Philadelphia.

CONTRIBUTIONS FROM THE PUBLIC SCHOOLS.—Although members of the medical profession are constantly doing little acts of charity for which there is seemingly no recompense, the good seed sown must surely bring forth its just reward. An example of what this means in dollars and cents, is seen in the penny contributions of school children for the benefit of sick soldiers in the different hospitals of this city and to be distributed as follows: Medico-Chirurgical \$584.80, St. Agnes \$408, University \$248.90, Presbyterian \$152.35, St. Joseph's \$145.55, German \$163.20, Episcopal \$115.60, St. Mary's \$58.50, Jefferson \$138.75, Hahnemann \$81.60, Polyclinic \$40.80, St.

Timothy \$8.18, Samaritan \$8.18, Women's Homeopathic \$54.40, Methodist \$36.75, other hospitals \$76.20. Total \$2,338.11.

SICK SOLDIERS.—There have been treated in all the hospitals of this city a total of about 2500 sick soldiers. Since September 12, Maj. D. C. Peyton, a brigade surgeon, has had full charge of the work here and has a corps of eight assistant surgeons to transact the business necessarily entailed upon that department. The following is the method of caring for the convalescents, according to the *Ledger*: "Men discharged from the hospital report first to the office with their hospital certificate, stating that they are convalescent. They are then given sick furlough and sent to the quartermaster, who furnishes transportation and commutation of rations at the rate of \$1.50 a day for the time necessarily taken in traveling to their homes. If a soldier is weak and has some distance to go, the quartermaster, on certificate from the surgeon's office, furnishes sleeping-car accommodations. If in need of clothing, he is furnished what is needed from the quartermaster's department on request of a surgeon. When hospitals notify the surgeon's office that certain soldiers are ready to be discharged, clothing is procured for them through the quartermaster's office and this is in many cases sent direct to the hospital, so that it is ready when discharge from the hospital is given.

MEMORIAL TO DR. JOSEPH LEIDY.—At a recent meeting of the Academy of Natural Sciences of Philadelphia, Dr. Edward J. Nolan presented a memorial of the late Dr. Joseph Leidy. The gift consisted of five volumes containing drawings and writings by that author. Dr. Leidy at one time practiced medicine in this city and for several years was professor of anatomy of the University of Pennsylvania, where he was much esteemed by the faculty and students. He is probably best known for his studies in the lower forms of animal life, comparative anatomy, and for his able and painstaking work of estimating the ages of stalactites and stalagmites of the Luray Cave, Virginia. Dr. Leidy was a thorough scientist, investigator and teacher, and his fame extends throughout the world.

LECTURE BY DR. ALBUTT.—Dr. Thomas Clifford Albutt, who has been traveling quite extensively in America and who occupies the chair of the theory and practice of medicine at Cambridge University, recently lectured to the graduating class of the University of Pennsylvania. The speaker was introduced by Dr. James Tyson, who lectured upon "Diseases of the Arteries in Association with Apoplexy." Dr. Albutt recently arrived from Baltimore, where he was the guest of Professor Osler of the Johns Hopkins University.

HOMEOPATHS WANT INSANE HOSPITAL.—At a meeting of the Homeopathic Medical Society of this city, at which time it is stated 100 delegates were in attendance, mention was made of the overcrowded condition of the insane asylums of the State of Pennsylvania. As matters now stand, these unfortunate are being cared for by the regular profession to the disadvantage of those who practice according to the tenets first promulgated (but not now practiced) by Hahnemann. In order to correct this discrimination a committee was appointed and instructed to use urgent means to have the subject brought before the proper legislative bodies. We await results.

TESTIMONIAL PERFORMANCE.—Arrangements are being made by members of the Ladies' Aid Society of the Medico-Chirurgical Hospital for a testimonial performance for the benefit of the sick soldiers in that institution. The Medico-Chirurgical has shown great enthusiasm in bringing the sick soldiers to the city through the medium of hospital trains, and deserves great credit for the manner in which it has increased its facilities on so short notice. This action, therefore, demonstrates the enterprise and capabilities of the men who comprise its managers and teaching faculty.

WANT OF CO-OPERATION.—Some time ago citizens of Germantown held a meeting, at which time a committee was appointed to devise ways and means for the erection of a children's hospital. It is stated, however, in the lay press that letters have been received from residents and business men who were appointed, declining to act as members of the board of directors. It is stated that contribution boxes have

been placed in different stores and offices for the benefit of the hospital fund, and committees have been appointed to draft rules and by-laws and to procure a charter. Invitations have been addressed to fraternal orders in Germantown asking financial aid for the institution.

EVADING VACCINATION LAW.—The fact has reached the board of health of this city that the compulsory vaccination law regarding school children is being evaded by the wholesale. A resolution has been passed by the board of education asking that the board of health be notified of the "large percentage of non-vaccinated children attending the schools, the children having been admitted upon certificates signed without proper evidence." It is further stated that the board of education has passed a resolution that the board of health be requested to disinfect the schools of this district or to provide the means for doing so. The disinfectant which was recommended was chlorid of lime and it was thought best to instruct the janitor in the proper use of this.

ADDITION TO SAMARITAN HOSPITAL.—Owing to the increased amount of work by this institution, the managers have decided to buy the dwelling house adjacent to the property and convert it into a department of the hospital. The entire property has a frontage of fifty feet and extends eastward a distance of 230 feet.

NEW MEDICAL LABORATORY.—Among the many other improvements going on at the University of Pennsylvania, another laboratory is to be built. To stimulate a spirit of friendly rivalry, Provost Harrison submitted the matter to the junior members of the architectural department for a proper design, but the jury of award has so far been unable to decide on whom the honor will be conferred.

VERDICT AGAINST TELEPHONE COMPANY.—Dr. John Marshall, dean of the Medical Department of the University of Pennsylvania, was recently awarded \$737 against the American Telephone Company for injuries sustained to shade trees at his summer home. In the construction of a line for the company along the estate some sixty or seventy alianthus and locust shade trees were destroyed, thus injuring the property.

REPORT OF THE NATIONAL RELIEF COMMISSION.—The National Relief Commission, which has so liberally provided for the sick soldiers in the field and in the hospitals of the different cities, has reported contributions of money and supplies aggregating thousands of dollars. The last report, made public by Mr. George C. Thomas, treasurer, at the banking house of Drexel & Co., is: Cash, etc., \$76,631.57; value of supplies to date, \$40,325.

MORTALITY STATISTICS.—For the week ending October 22, there were reported to the Bureau of Health a total of 389 deaths, of which 122 occurred in children under the age of 5 years. The total number of deaths is an increase of 58 over that of last week and an increase of 13 over the corresponding period of last year.

SOLDIER PATIENTS.—The government recently transferred twenty five sick soldiers from Camp Meade to this city, where they are being treated at the Woman's Hospital.

SOCIETY FOR FIRST AID TO INJURED.—A society has recently been formed here for the purpose of giving instruction in "home nursing" and to render "first aid to the injured." Lectures will be given at stated times in suitable rooms, both in this city and throughout the State of Pennsylvania.

RECEPTION.—Members of the Philadelphia Medical Club recently tendered a reception to Dr. W. L. Rodman, professor of surgery in the Medico-Chirurgical College. A representative body of physicians attended.

RED CROSS HOSPITAL.—Members of the Red Cross Society of this city have secured a site for a hospital at the corner of Twentieth and Cherry Streets, and are rapidly putting in equipments necessary for the care of patients soon to be admitted. A committee has been appointed, consisting of several physicians and lay members, who will act as the board of managers.

Louisville.

GARVIN.—Dr. Samuel H. Garvin has just been re-elected jail physician for the ensuing four years. The place is awarded by vote of the justices of the peace of Jefferson County. Dr. Garvin is a native of Louisville, and has spent the best part of his life in this city. He has served as jail physician nearly twenty-two years, under both republican and democratic administrations. There was but one opposing candidate.

MORGAN.—Dr. L. C. Morgan of Duganville was the victim of a dastardly attempt at robbery on the 4th inst. While on

his way home from a neighboring town, about 10 P.M., he was decoyed into a house by three negro men, who told him a colored woman was very ill and in need of a physician's services. When the Doctor entered the house the negroes set upon him for the purpose of robbery. The Doctor drew a pistol, but one of his assailants shot him with both barrels of a shotgun before he could make any resistance. He remained conscious long enough to give a description of his assailants, and they are now under arrest and close guard, as there is great talk of lynching.

KOEHLER.—Dr. Henry H. Koehler has announced that his practice will be limited to genito-urinary and skin diseases from this time, with an office at 1001 Fourth Avenue.

JOHNSTON.—Dr. Geo. Ben Johnston of Richmond, Va., en route to the Mississippi Valley Medical Association, where he delivered the address in surgery, was the guest of Dr. L. S. McMurtry at a dinner on the evening of the 10th.

MEDICO-CHIRURGICAL SOCIETY.—This society's membership has been depleted by the death of Dr. John A. Larrabee, and the resignation on account of removal from the city of Drs. Wm. L. Rodman and Jno. L. Howard. Dr. P. L. Butler and Dr. T. C. Evans have been elected for two of the vacancies, and Dr. H. H. Grant is in nomination for the third.

MARVIN.—Dr. J. B. Marvin and family have returned from a three-months' sojourn in Europe.

PHARMACY.—The regular meeting of the State Board of Pharmacy was held in Frankfort, last week, for the purpose of examining applicants for license.

QUARANTINE.—Upon the advice of the State Board of Health, the Commercial Club, one of the principal organizations of business men in the city, has issued a proclamation, inviting yellow fever refugees from the South to Louisville, as was done last year. As a result there has been a great number of the Southern residents in the city during the past three weeks.

CATTLE.—Drs. F. T. Eiseleman and J. G. Gashin, respectively State veterinarian and State bacteriologist, have returned from the meeting of the Interstate Association of Live Stock Sanitary Boards, and are preparing their report for submission to the governor, in regard to "tick" cattle. One of the chief points developed at this meeting was the fact that cattle dipped in dynamo oil and sulphur can be safely mixed with northern cattle, and when inspected by either State or Federal authorities, can be shipped north at any time of the year. It was decided that the open season should extend from November 1 to January 1, when cattle can be shipped north for immediate slaughter. It was determined to ask the Secretary of Agriculture to so change the quarantine laws of Oklahoma, Kansas, Missouri, Tennessee and Texas that cattle from all points below the quarantine line may not be shipped to points above the quarantine line, unless intended for immediate slaughter. The only way cattle may be admitted above the quarantine line is by inspection by Federal and State authorities after being dipped. A resolution in line with the above was sent the Secretary of Agriculture by the Louisville Live Stock Association endorsed by the State Board of Health.

STATE BOARD OF HEALTH.—The State Board of Health held its annual session at the Galt House on the 20th inst., with the following members present: J. M. Mathews, president; J. N. McCormack, secretary, of Bowling Green; J. H. Letcher of Henderson; J. H. Samuel of Maysville and Wm. Bailey of Louisville. The report of Secretary McCormack was a review of the Board and detailed much important work done, characterized by the Secretary as the most active and anxious in the history of the Board. This anxiety was caused by the yellow fever epidemic in the South and the number of refugees passing through the State; the prevalence of smallpox which was so widely epidemic in the State and in separated districts. The inspection service of the Board and disinfection on board trains was reviewed by the report, and the obstacles thrown in the way of the Board by one railroad was mentioned. Attention was called to the fact that the epidemic of smallpox necessarily made a heavy drain on the appropriation of the Board, and that it is practically without funds at present. It was stated that the General Assembly is adding new work to the Board every year, but is making no increase in the appropriation. The increasing prevalence of scarlet fever, diphtheria and typhoid fever was mentioned, and the alarming death rate from these causes, causing more deaths than yellow fever and cholera have in the history of the State. Dr. McCormack commended the work of the State veterinarian in cases of Texas fever, anthrax and glanders which have appeared among the cattle and horses in the State. It was stated that owing

to the increase of the routine work of the executive officer of the Board it would become necessary shortly for him to devote his whole time to it. The amount expended by the Board was \$3,544.20. Action was taken at this session on the cases of several who have been guilty of unprofessional conduct or quackery in the State. Dr. Adaline Bell of Paris, who appeared before the Board to stand the required examination for candidates to practice osteopathy, had failed to come up to the standard in the subjects upon which she was examined, and she was refused a license. Dr. G. N. Murphy of Bowling Green, who claims to cure what physicians generally recognize as incurable, and guilty of other unprofessional conduct, was represented by an attorney and his case set for hearing on November 7. Mr. Aaron Kohn, attorney for the Board, presented the report as an answer to Harry Nelson, who has been practicing osteopathy. The answer says for the Board that osteopathy is simply a perfected system of quackery and empiricism, and denies that it requires any learning or ability to "become versed in the pretended doctrines" of the system. The reply says that Nelson has never applied to the Board for a license to practice and has refused to submit himself or his qualifications to the provisions of the statute enacted by the legislature. The reply concludes that to allow Nelson to practice would be to sacrifice the lives, health and limbs of the citizens of Kentucky. Notice was prepared to be served on P. H. Woodhull of Bowling Green, also an osteopath, to appear before the Board on November 8, and answer charge of unprofessional conduct. The Board adjourned to meet again on November 7.

CHLOROFORM.—A death from chloroform occurred at St. Joseph's Infirmary on the 20th inst. The patient was a policeman who was to have a toe amputated, and was found in good condition to take an anesthetic, which was administered by the interne of the hospital. There was a prolonged stage of excitement and much struggling and the patient died in this state before the operation had been begun.

DRUGGISTS.—Several of Louisville's retail druggists have just returned from St. Louis, where they attended a meeting at which the National Retail Druggists' Association was organized. The Louisville druggists represented the Louisville Botanical Association and the Kentucky Pharmaceutical Association. One of the representatives, in an interview, stated that much was done at the meeting which would aid the druggists of this city in getting away from the cut-rate business, which has demoralized the retail drug trade in the past two years. Resolutions were adopted calling upon manufacturers to cease selling to department stores, to rabid cut-rate druggists and to retailers in large quantities. They also requested the assistance of all retailers and jobbers and manufacturers in having the medicine tax remitted, or if that be not possible, to have the Government remit the tax on such simple remedies as druggists may put up themselves according to public formulae. This meeting was held at the time the Wholesale Druggists' Association and National Proprietary Medicine Manufacturers were in session, yet the roll call showed twenty-one States represented and about 150 in attendance.

THE PUBLIC SERVICE.

Movements of Army Medical Officers. The following named officers have been ordered to duty in connection with the mustering out of volunteer commands: Major Ezra Woodruff, surgeon U. S. A., Ft. Trumbull, Conn., for Rhode Island Vols.; Major Augustus A. De Loffre, surgeon U. S. A., Austin, Texas, for Texas Vols.; Major Charles K. Winne, surgeon U. S. A., Ft. Crook, Neb., for Nebraska Vols.; Major W. F. de Niedeman, brigade surgeon U. S. V., to Jefferson Bks., Mo., for the 1st Missouri Inf.; Major Timothy E. Wilcox, surgeon U. S. A., to New York City, for New York Vols.; Major Louis W. Crampton, surgeon U. S. A., Ft. McHenry, Md., for the 5th Maryland Inf.; Major Geo. W. Crile, brigade surgeon U. S. V., from Cleveland, Ohio, to Ft. Sheridan, Ill., for the 1st Illinois Cav.; Major Elmer E. Heg, brigade surgeon U. S. V., from the general hospital, Ft. Myer, Va., to Omaha, Neb., for the 2d Neb. Inf.; Major John P. Dodge, brigade surgeon U. S. V., from Camp Wikoff, Montauk Point, L. I., to Columbus, Ohio, for Ohio Vols.; Major Eugene L. Swift, brigade surgeon U. S. V., from Camp Wikoff to Concord, N. H., for New Hampshire Vols.; Capt. Chas. Wilcox, asst.-surgeon U. S. A., to Columbia, S. C., for South Carolina Vols.; Capt. Chas. Lynch, asst.-surgeon U. S. A., from Camp Frank Ardmore, Ind. Terr., to Little Rock, Ark., for the 1st Arkansas Inf.; Capt. Henry D. Snyder, asst.-surgeon U. S. A., from Ft. Ethan Allen, Vt., to Burlington, Vt., for Vermont Vols.; First Lieut. Weston P. Chamberlain, asst.-surgeon U. S. A., from the general hospital, Ft. Monroe, Va., to Richmond, Va., for the 3d Virginia Inf.; and Acting Asst.-Surgeon Alexander McF. McMasters, his orders to Cuba being revoked, to Philadelphia, Pa., for Pennsylvania Volunteers. Capt. Francis A. Winter, asst.-surgeon U. S. A., and Acting Asst.-

Surgeon S. M. Long from Camp Wikoff, Montauk Point, L. I., to New Haven, Conn., for Connecticut Vols.; Capt. Wm. F. Lewis, asst.-surgeon U. S. A., from Huntsville to Montgomery, Ala.; Capt. C. E. B. Flagg, asst.-surgeon U. S. A., from Ft. McPherson, Ga., to Montgomery, Ala.; and Acting Asst.-Surgeon Robt. N. Pitts, now at Montgomery, Ala., for Alabama Vols.; Major Jas. M. Jenne, chief surgeon of volunteers, from St. Albans, Vt., and Capt. Geo. J. Newgarden from Ft. Adams, R. I., to Boston, Mass., for Massachusetts Vols.; Major Chas. R. Parke, brigade surgeon volunteers, from Camp Meade, Middletown, Pa., to Augusta, Me., and Capt. H. R. Stiles, asst.-surgeon U. S. A., to Ft. Preble, Me., for the 1st Maine Inf.; Major Robert Burns, brigade surgeon volunteers, to Concord, N. H., for New Hampshire Vols.; Lieut. Samuel M. Waterhouse, asst.-surgeon U. S. A., to Ft. Logan H. Roots, Ark., for the 1st Arkansas Inf.; Acting Asst.-Surgeon Arlington Pond from Ft. Myer, Va., to Richmond, Va., for the 3d Virginia Inf.

Relieved from duty with field commands and ordered to posts: Lieut.-Col. Benjamin F. Pope, chief surgeon U. S. V., to Columbus Barracks, Ohio; Major Chas. L. Heilmann, surgeon U. S. A., from Camp Wikoff, N. Y., to Fort Adams, R. I.; Major Henry S. Kilbourne, surgeon U. S. A., to Madison Bks., N. Y.; Major Marshall W. Wood, surgeon U. S. A., to Fort Douglas, Utah; Major Rudolph G. Ebert, surgeon U. S. A., to Vancouver Barracks, Wash.; Major W. C. Burden, brigade surgeon U. S. V., to Washington Barracks, D. C.; Major Walter D. McCaw, brigade surgeon U. S. V., to Fort Porter, N. Y.; Major Francis J. Ives, brigade surgeon U. S. V., to Willets Point, N. Y.; Major Guy L. Edie, brigade surgeon U. S. V., from the 1st Army Corps at Lexington, Ky., to the Presidio, San Francisco, Cal.; Major Chas. B. Ewing, brigade surgeon U. S. V., to Fort Brady, Mich.; Majors Aaron H. Appel and Paul Shillock, surgeons U. S. A., to Fort Grant, Arizona; Major Eugene L. Swift, brigade surgeon U. S. V., from mustering-out duty in New Hampshire to Fort Slocum, N. Y.; Major Louis S. Tesson, U. S. A., to Fort Ethan Allen, Vt.; Capt. Henry R. Stiles, asst.-surgeon U. S. A., to Fort Preble, Me.; Capt. Geo. J. Newgarden, asst.-surgeon U. S. A., to Fort Adams, Vt., and the following acting asst.-surgeons: Joseph M. Miller from Camp Wikoff, N. Y., to Fort Ethan Allen, Vt.; O. C. Heise and Milton D. Norris from the Sternberg Hospital, Chickamauga Park, Ga., to Jefferson Barracks, Mo.; and James T. Arvine to Fort Ringgold, Tex.

To Camp Meade, Middletown, Pa.: Major Junius L. Powell, surgeon U. S. A., from Camp Wikoff, N. Y., and acting assistant-surgeons Wm. Alden from Portland, Me., and Dwight B. Taylor from Camp Poland, Knoxville, Tenn.

To the 7th Army Corps, Gen. Fitzhugh Lee, Jacksonville, Fla.: Major W. Fitzhugh Carter, surgeon U. S. A., from the 4th Corps at Fernandina, Fla., and the following acting assistant-surgeons: Geo. G. Chaim and William S. Terriberry from Washington, D. C.; John D. Thomas from Charleston, S. C.; Frederick R. Dolsen from Fort St. Philip, La.; John Lyng from Kensington, Minn.; Thomas R. Marshall from Camp Wikoff, N. Y.; Thomas V. Aby from Fort Lawrence, Kas., and William E. de Salazar from New York City.

To Camp Poland, Knoxville, Tenn.: Major Adrian S. Polhemus, surgeon U. S. A., and acting asst.-surgeons John B. Alcorn and Hyman Finklestone from Washington, D. C.; William P. Lawrence from Nashville, Tenn., and John B. Hallwood from New York City.

To duty with troops at Camp Hamilton, Ky.: Major John M. G. Woodbury, chief surgeon U. S. V.; Acting Asst.-Surgeon James W. Madara from the Fort Thomas General Hospital, Ky.

To the General Hospital, Fort McPherson, Ga.: Acting Asst.-Surgeons Ernest W. Fowler, Robert C. Rind and Victor E. Watkins from the Sternberg Hospital, Chickamauga, Ga.

To the General Hospital, Fort Thomas, Ky.: Acting Asst.-Surgeon Arthur E. Smith from Ravenna, Ohio.

To duty with troops at Huntsville, Ala.: Major R. J. Gibson, surgeon U. S. A., from Fort Meade, S. D., to the 8th U. S. Cav.; Lieut. Guy C. M. Godfrey, asst.-surgeon U. S. A., to the 10th U. S. Cav.; Lieut. Albert E. Truby, asst.-surgeon U. S. A., to the 8th U. S. Inf.; Lieut. James M. Kennedy, asst.-surgeon U. S. A., to report to the commanding general; Acting Asst.-Surgeon Wm. B. Winn from Fort Niagara, N. Y., to the 8th U. S. Cav., and the following acting asst.-surgeons to report to the commanding general: A. H. Simonton from Camp Wikoff, N. Y., and Chauncey T. Scudder and G. J. de Quesada from Washington, D. C.; T. H. Lander from the Sternberg Hospital, Chickamauga Park, Ga., and W. C. Douglas from Camp Wikoff, Montauk Point, L. I.

To the Josiah Simpson General Hospital, Fort Monroe, Va.: Capt. Benjamin Munday, asst.-surgeon U. S. A., from Jacksonville, Fla.; Lieut. Powell C. Fauntleroy, asst.-surgeon U. S. A., and Acting Asst.-Surgeons W. H. Prescott and Raphael A. Edmondston from Camp Wikoff, Montauk Point, L. I.

To duty with troops at Anniston, Ala.: Lieuts. and asst.-surgeons U. S. A., Henry A. Webber to the 1st U. S. Inf. and Edward T. Schreiner from the General Hospital, Fort McPherson, Ga., to the 2d U. S. Inf. Acting Asst.-Surgeon Peter Beckman to duty with the 2d U. S. Inf., and the following acting asst.-surgeons to report to the commanding general: Frank G. Jones and Charles I. Woolford from Washington, D. C.; Rufus D. Boss from Camp Wikoff, N. Y., and Pemberton Lundy from Buffalo, N. Y.

To the 7th Army Corps at Jacksonville, Fla.: Major Ezequiel de la Calle, brigade surgeon U. S. V. from New York City, N. Y., and Acting Asst.-Surgeons Vernon J. Hopper, Henry B. Stotter and Benjamin A. Kittrell from Washington, D. C.

To Santiago, Cuba, via New York City: Louis A. Moloney, acting asst.-surgeon from Cincinnati, Ohio, and Acting Asst.-Surgeon Edward R. Bragg from Camp Wikoff, N. Y.

To Ponce, Porto Rico: Major Louis Brechemin, surgeon U. S. A., and Acting Asst.-Surgeons Charles S. Stern from Camp Geo. H. Thomas, Chickamauga, Ga.; Capt. Frederiek P. Reynolds, asst.-surgeon U. S. A., and Acting Asst.-Surgeon John W. Wright from Fort Monroe, Va., his previous orders to Santiago having been countermanded.

To Havana, Cuba: Lieut.-Col. R. M. O. Reilly, chief surgeon U. S. V., as a member of a board under orders from the Secretary of War, and Acting Asst.-Surgeon Joaquin L. Duenas from Philadelphia, Pa., to duty with the board to select camp sites.

On sick leave: Major Philip G. Wales, brigade surgeon U. S. V. from Camp Wikoff, N. Y.; Major Peter D. McNaughton, brigade surgeon U. S. V.; Major Charles B. Ewing, brigade surgeon U. S. A. from Camp Geo. H. Thomas, Ga.; Capt. Geo. M. Wells, asst.-surgeon U. S. A.; Capt. Chas. F. Kieller, asst.-surgeon U. S. A. from Camp Wikoff, N. Y.; Capt. George H. Wichter, asst.-surgeon 8th Ohio Inf.; Capt. O. B. Weed, asst.-surgeon 32d Mich. Inf.; Lieut. Thos. S. Kirkpatrick, asst.-surgeon U. S. A. from Santiago, Cuba, and the following acting asst.-surgeons: Peter M. Beckman, Geo. L. McLeod, Wm. E. Stemen and James S. Kennedy from Camp Wikoff, N. Y.; Major Marshall W. Wood, surgeon U. S. A.; Majors and Brigade-Surgeons U. S. G. S. William B. Bannister, Guy L. Edie and Frank Bruso; Major W. C. Gorgas, surgeon U. S. A.; Major E. D. Bain, surgeon 2d Ohio Inf.; Lieut. Cassius C. Hogg, asst.-surgeon 1st West Va. Inf., and Acting Asst.-Surgeon John E. Bacon.

To be examined for promotion: Wm. W. Quinton, Thomas S. Bratton Deane C. Howard, Wm. H. Wilson, James M. Kennedy and Guy C. M. Godfrey, asst.-surgeons U. S. A.

Resigned: Capt. A. J. Pedlar, asst.-surgeon 1st Batt. Cal. Heavy Art.; Lieut. Rowland B. Robinson, asst.-surgeon 1st R. I. Inf., and Lieut. Stephen J. Keefe, asst.-surgeon 3d N. J. Inf.; Major Charles C. Foster, surgeon 5th Mass. Inf.; Capt. B. H. Kitrell, asst.-surgeon 1st Miss. Inf.; Capt. Ira B. Ladd, asst.-surgeon 7th Cal. Inf.; Capt. Seth S. Ulrich, asst.-surgeon 1st Md. Inf.; Lieut. James R. McCausland, asst.-surgeon 1st Del. Inf.; Lieut. C. William Newton, asst.-surgeon 10th Ohio Inf.; J. Wilson Poucher, asst.-surgeon 201st N. Y. Inf., and James N. McLean, asst.-surgeon 2d Ala. Inf.

Honorably discharged: Lieut.-Col. Benj. F. Pope (Major and surgeon U. S. A.) as chief surgeon volunteers only; Lieut.-Col. Rush Huidekoper, chief surgeon volunteers; Major Jabez N. Jackson, brigade surgeon volunteers; Majors Thos. Earle Ewins and Lewis Schooler, chief surgeons volunteers; Major Wm. Arthur (Captain and asst.-surgeon U. S. A.) as chief surgeon volunteers only; Major Robert Burns, surgeon 1st New Hampshire Inf., to accept commission as brigade surgeon volunteers, and Lieut. John H. Gibbons, asst.-surgeon 3d U. S. V. engineers; Major Leonard B. Almy, chief surgeon volunteers, and Majors Milo B. Ward and Calvin H. English, brigade surgeons of volunteers.

CHANGE OF ADDRESS.

Brandenburg, L. A., from 2348 Hickory to 2900 Eads Avenue, St. Louis, Mo.

Bartlett, J., from 462 E. Division to 281 Oak Street, Chicago, Ill.

ADDRESS.

PROGRESS IN NEUROLOGY.

[ABSTRACT].

Chairman's Address before the Section on Neurology and Medical Jurisprudence at the Forty-ninth Annual Meeting of the American Medical Association, held at Denver, Colo., June 7-10, 1898.

BY C. H. HUGHES, M.D.

ST. LOUIS.

Since last we met Neurology continues its onward march, both in special discovery and in new and better precepts and principles to guide the practice of our art.

During the past year the neurologic view of heart disturbance finds further confirmation from physiologic sources in the following recent editorial reference to the subject in the *Duetsche Wochenschrift*:

"A series of experiments at Buda Pest, producing artificial valvular insufficiency and dividing the vagi, seems to demonstrate that alterations in the nervous system play an important part in preventing compensation in cases of valvular insufficiency."

Numerous clinical symptoms confirm this assumption; arrhythmia, etc., and Ott's statement that he found the nerve-cells degenerated in cases of "incompensation."

The direct neural and reflex nervous disorders of the heart constitute our chief concern in clinical medicine, and damage to the vagus and upper abdominal viscera constitute the chief concern in the management of most cardiac affections, as the neurologist, the alienist, and even the general practitioner, encounter them in practice.

The past year has witnessed more attention to psychiatry on the part of neurologists and more attention to pathologic work, as instance in illustration, the wide range of subjects treated in the State Hospitals Bulletin of New York, a publication which bids fair to become as famous for record of good work as the well-known and unsurpassed West Riding Asylum Reports of Great Britain.

A committee of the American Neurologic Association has since our last meeting taken up and reported to that body on the subject of the after-care of the insane.

In this connection, I note that Dr. Putman of Boston, in the Transactions of the Association of American Physicians and in the *American Journal of Medical Sciences*, offers new views of thyroïdal diseases and Graves' disease, and Dr. J. T. Eskridge of Denver also on some new uses of the thyroid extract. Our colleague of this city, who never rests from his labors, will soon be heard from in the *American System of Practical Medicine*, Vol. iv., now in press, and has reported in the September *Medical News*, an interesting case of intradural spinal tumor, extending through the foramen magnum, compressing the extreme upper

portion of the cord and almost completely destroying it at the third cervical segment.

Up to 1884, Drs. Goodell, Pallen and other gynecologists advised the removal of the ovaries in all cases of insanity.

That same year, Dr. T. G. Thomas reported three cases of insanity following the operation and Dr. Putzel, of the New York City Lunatic Asylum, reported one hundred postmortems on insane women dying in that institution without a trace of disease of the ovaries.

Since our protest in 1882 (vide *Alienist and Neurologist*, January of that year) against the too reckless surgical disposition then in vogue to "obliterate the neuropathic constitution by excising the ovaries" and the later protests of our neurologic colleagues, a sensible conservatism has supplanted reckless radicalism concerning this operation which Spencer Wells, Matthews, Duncan and Martin of Berlin early discountenanced.

The entire editorial under the caption of "Unjustifiable Pelvic Operations" is a further evidence of the invasion of neurologic thought into the domain of general clinical medicine and surgery especially during the past year, and confirms our long ago expressed conviction (vide *Alienist and Neurologist*, 1880) that "Neurology is destined to reign paramount in medical thought and practice."

Playfair, a professor of obstetric medicine in Kings College, contributes a chapter to Allbutt's English and American Gynecology, and Howard Kelly, our own countryman, in a late number of the *American Journal of Medical Sciences* opposes needless vaginal examinations and repeated local treatments of virgins from a psychical standpoint, as any neurologist might.

The year since last we met therefore closes with the prevalent and advanced professional conviction, no longer confined to neurologists alone, that the neuropathic diathesis is not removable by the knife.

The influence of magnetic stress on physiologic action as a part of neurotherapy is worthy of note here, and on this subject our colleague, Prof. W. J. Herdman, in the *Bulletin of the Electro-Therapeutic Laboratory of the University of Michigan*, in his capacity as director thereof, called attention to this subject, October, 1887, showing a 10 per cent. daily increase of eliminated urea on the days when subjects were in the magnetic field and upon animals, 20 per cent. of increase of nutrition for eight weeks while in the magnetic field, with a gradual decline after the twelfth week, showing tolerance. These results correspond with d'Arsonval's.

The surgical treatment of exophthalmic goiter was the subject of discussion at the French Surgical Congress, Paris, October, 1897. M. Faure of Paris reported having excised the cervical sympathetic in three cases. In the first of these, the superior cervi-

cal ganglion, along with five or six centimeters of the descending cord, was excised on both sides; after four months the exophthalmus had diminished, the goiter was less in size, the tachycardia and the general health had much improved. In the second, the entire sympathetic was resected on the right side (superior and inferior ganglion included), the superior ganglion and part of the cord only on the left side (because of the onset of alarming syncope); this patient improved still more markedly than the first. The third case died on the table after the entire sympathetic cord had been removed from the right side and the dissection on the left side was about to begin.

I introduce this record of so-called progress in surgical neurotherapy only to enter my protest against M. Faure's procedure. The improvement resulting in the first two recorded cases was not greater than would have come to the victims of his knife under the enforced rest and expectancy of the operation, and the spinal sympathetic system is not so useless in the human economy as to justify such radical destruction. This, the death on the table of the third case operated upon confirms.

I oppose this surgical procedure also because it is not only too destructive, but because it is not necessary, since exophthalmic goiter is almost invariably curable without the knife, at least it has been so in my hands under arseniated and phosphorated bromid and blood reconstructive treatment, with adequate nerve and brain rest and changed mental environment for the patient.

Something has been added to the therapy of neuropathy during the past year. The suspension treatment of tabes modified by recumbent knee-abdomen process and stretching of the sciatic nerve in sciatica, have passed from a great therapeutic expectation to their normal remedial limitations, and the much-heralded massage cure for tabetics is now on the tapis to find the sphere of legitimate limitation during the coming year, just as is the fate of all therapeutic fads.

Spermin (Poehl's *Deutsche Medicinische Wochenschrift*, Oct. 7, 1897) has been used with benefit by Wesbitzky of Professor Payoff's clinic in St. Petersburg. One of his cases, a soldier of sixty years of age, after ten injections, improved markedly in gait, posture, pains and perception (tactile and electric), etc. A second case not so typical, improved, but not so markedly.

Many new cures for epilepsy have been emblazoned on the therapeutic horizon during the past year, but none have yet eclipsed the Brown-Sequard formula.

Among the latest additions abroad to the therapy of this disease is an old remedy long used in this country before the advent of bromids, viz., adonis vernalis.¹

The Johns Hopkins Hospital Reports, *The Journal of Psychology and Comparative Physiology* and the *Ophthalmologic Review* have contributed much during the past year to neurologic progress, and thyroid-therapy has been much extended in its usefulness in neurology, but my twenty minutes' limit will not permit me to dwell more at length on this subject.

The after-care of the insane, separate provision for epileptics, sequestration in hospital colonies, the increased attention given to the subject of asexualization for incurable and propagable and criminal neuro-

pathic disorders, mark neurologic progress during the past year and give hope of the staying of that neuropathic plague which, like a silent pestilence, has followed and damaged civilization in its march since its emergence from barbarism.

The literature of psychiatry in this country has been enriched also by a book by Dr. Kellogg on, "Mental Diseases," Dr. Chapin's "Compendium of Insanity," John C. Shaw's "Compendium of the Essentials of Nervous Diseases and Insanity," and S. V. Clevenger's treatise.

The advancing popular professional interest in psychiatry is further shown by the advent of Burr's "Primer of Psychiatry for Medical Men and Students and Trained Nurses," and the frequent contributions to the psychiatric aspects of the practice of medicine and surgery from sources of clinical experience where until lately these subjects were persistently ignored.

Physiologic and neurologic medicine during the past year has elicited unusual interest in the general medical societies of the country. Chas. E. Beavor, H. K. Lewis, Mills and Dana, of this country, have since last we met, brought out new books on the diseases of the nervous system.

The normal histology and pathology of the neuroglia (so-called) in relation especially to mental diseases has been much elucidated during the past year by Dr. W. F. Robertson's report from the laboratory of the Scottish asylums in addition to the contributions of other American and European asylums, especially the Italian.

The neuron is a proved unit in physiologic and pathologic processes and Lewellys F. Barker has done more than any other American during the past year to prove it.

Foster and Sherington have embodied the discovery of Raymon Y. Cajal, and the later amplifications of this new light on the nerve-centers, in a new edition of Foster's text-book of physiology. Dercum has offered some captivating conceptions thereon which do not yet appear as misconceptions, and Van Geison continues his researches to the glory of American neurology.

I think it was Weidersheim who, in 1890, saw or thought he saw movement under the lens in an esophageal ganglion of a living animal. The mobility of the neuron was suggested by Rabe-Ruckard and Lapine and Duval.

Pierce Bailey's book, just from the press of D. Appleton & Co., on accident and injury in their relation to the nervous system, is the beginning of that surgical *rapprochement* between surgery and neurology which needs only to be supplemented by the forthcoming book from the neurologic side on the relationship of the nervous system to accidents and injuries, especially in its pathologic states, to make the union complete.

Neurology in its neuro-physiologic and neuropathologic aspect is destined to again unite all the specialties to that general medicine from which they have been prone to become too much dissevered. We have progressed already to the point that binds neurology more or less closely to all clinico-medical and clinico-surgical problems. The labors of neurology in the medical advance of the nineteenth century have not been in vain.

¹ Tekutiew, in *Neurologisches Centralblatt*, February, 1898,

ORIGINAL ARTICLES.

HEREDITARY SYPHILIS.

Presented to the Section on Diseases of Children, at the Forty-ninth Annual Meeting of the American Medical Association, held at Denver, Colo., June 7-10, 1898.

BY L. DUNCAN BULKLEY, A.M., M.D.

PHYSICIAN TO THE NEW YORK SKIN AND CANCER HOSPITAL; ATTENDING PHYSICIAN TO THE SKIN DEPARTMENT, RANDALL'S ISLAND; CONSULTING PHYSICIAN TO THE NEW YORK HOSPITAL, ETC.
NEW YORK CITY.

This topic is one of great practical interest. Fournier has wisely remarked that "nothing is so dangerous to its surroundings as a syphilitic infant,"¹ and it can not be without interest and value to discuss a subject so vitally connected with the welfare of many of those whom we are called upon to treat. The subject of hereditary syphilis is such a vast one that it is difficult to determine just what points to present; and each aspect is capable of development far beyond the proper limits of these introductory remarks.

First, it may be said that our consideration will be confined to *hereditary* syphilis, as distinguished from the broader subject of *infantile* syphilis; for the latter properly includes that acquired after birth in innumerable ways, such as in nursing, feeding, vaccination, circumcision, and many others, and even a primary sore acquired while passing through the mother's parts.

It may be here remarked that Fournier² has made the distinction between syphilis received with conception—that is, when one or both parents were diseased before procreation—and syphilis acquired by the fetus during intra-uterine life, from a subsequent infection of the mother. To the former alone he would apply the term "hereditary" syphilis. He claims that clinically there is a difference to be observed between the ante-conceptual syphilis and that acquired during intra-uterine life; the former is much more fatal to the fetus. In our study we shall not make this discrimination, but for practical purposes consider hereditary as synonymous with congenital syphilis.

Confining our attention then, to hereditary syphilis, or that existing at birth, there are many very interesting points which meet us at the threshold of our study and are not without practical bearing; some of these are still "moot points," and can not be absolutely determined; some lead us so far away from the center point—the syphilitic infant—that they need not be included. We will consider a few of those most vitally related to the subject.

The first question that arises is: How and when does transmission of the disease take place? When the mother is profoundly syphilitic in the early contagious period of the disease, it is not difficult to understand that her offspring should partake of the same. But what are the limitations of time or condition as to the date of the mother's infection? This is a hard question to answer absolutely. Many cases are on record when the mother has acquired the disease one, two, three, five, seven and even eight months after conception, with the result of either abortion or a syphilitic child; I am not aware of any reported cases where infection in the ninth month resulted in a diseased child, and generally it will escape an eighth month infection. Naturally, syphilis acquired before conception will be more likely to cause early abortion; that received later results in a diseased child.

The more difficult question as the direct effect of only paternal transmission of syphilis can not be so easily and certainly dismissed. Many have doubted if the disease could be given by the father alone, without the intermediate infection of the mother, for certain reported experiments have seemed to indicate that the syphilitic virus is not communicated by means of the normal secretions—milk, saliva and semen. On the other hand, clinical evidence is accumulating that many children with syphilitic fathers are born with the disease, while the mothers are free from it—or appear to be free from it, on careful and prolonged medical observation. Some writers have attempted to explain away these cases by the well-known irregularities of syphilis, whereby, especially in women, its course may be peculiar, with prolonged absence of active symptoms. But still other clinical facts are being presented which go far to support the paternal transmission of the disease. Such are the occasional exceptions to Colles' law, in which the mother has been infected by her own child, and also instances of her acquiring a chancre otherwise (after having given birth to the syphilitic baby); both of these show that she has not the disease at the time, and so the infant's infection must have come from the father. Instances are also on record where a woman has borne syphilitic children to syphilitic men, and healthy children to healthy men. The paternal transmission of syphilis must, therefore, be accepted as a fact.

Syphilis is a powerful poison, producing various degrees of vital injury, even to death. It is not necessary to discuss here the nature of the virus, about which very little is positively known; most observers agree that it must be due to a toxin dependent on a micro-organism, which, however, has not as yet been isolated with certainty. The first effect of a full dose of the poison is inhibitive to the powers of procreation, and sterility is the fortunate result. With a slightly less intensity of the virus a non-viability of the product of conception results, and the fetus is thrown off early, even before the third month. With diminished virulence of the poison, or greater vitality of the parents, the life in the uterus will be prolonged, and abortion of a fully-formed and diseased child may take place at any period up to full term: but by far the larger number of miscarriages take place by or before the seventh month. With still less of the poison or greater vital resistance, the child may be born at full term, with or without external manifestations of the disease.

Even if brought into the world alive, the product of syphilitic conception has a relatively weak hold on life. This is instanced in the well-known statistics of the Moscow Hospital, where of 2000 syphilitic children born in eleven years, over 70 per cent. died. Fournier makes the mortality 28 per cent. from exclusive paternal heredity, 60 per cent. from maternal heredity, and 68.5 per cent. from a mixed heredity. Some figures are even more appalling. In Sigmund's wards in Vienna, out of 61 children born syphilitic, 59 died, 13 of them being still-births; of 47 living children only 4 survived more than three months. These figures, however, relate to hospital cases, and were taken some years ago, and it is believed that, with better knowledge of the disease and prophylactic treatment, a very much better showing could now be made; the results are also much better in private practice. But the facts stated serve to show the terrible virulence of the poi-

¹ Fournier: Syphilis et Mariage, p. 211. Paris, 1880.

² Fournier: L'Herédité Syphilitique, Paris, 1891.

son when operating under adverse circumstances, or unchecked, and forcibly point to the necessity of the most extreme care in many directions in connection with syphilis and married life. As such may be enumerated: complete treatment before procreation is attempted; very thorough treatment up to the very hour of confinement, where syphilis exists; the very early recognition and vigorous treatment of the disease in the child; and, moreover, a very guarded prognosis in every direction, whenever there is any syphilitic element in connection with the case.

When the syphilitic child is born alive it may appear profoundly affected by the disease or may have almost or quite the appearance of a healthy child; when born diseased it scarcely survives even many days, death resulting from cachexia and gastro-intestinal trouble, largely dependent on visceral lesions. In the child dying thus early from inherited syphilis very great changes are found in the internal organs, which we have hardly time to mention here. The liver is enlarged and hard, due to fibro-plastic matter, whereby the capillaries are often obliterated, with compression of the cells of the acini and consequent cessation of the secretion of bile. Or there may be other alterations which need not detain us here. The spleen is found to be enormously enlarged, more than double in size, and hard, also with syphilitic endarteritis. The lungs are affected by much the same process, that is, with new formation of connective tissue surrounding the bronchioles and also the capillaries, interfering with circulation and expiration. By this means nodules form in the plugged and distended alveoli, which break down, forming fatty or caseous masses that may involve much of the lung. Almost all of the internal organs, and even the bones, have been found to be affected by more or less similar processes, so that the child born dead with syphilis, or dying soon after, is literally infected throughout with the poison, of which the skin symptoms, which may or may not be prominent, are only a single feature, and that not the most important, except for diagnostic purposes.

If now, the poison is not in excess, or if the vitality is very great, the infant may be born in an apparently healthy condition, and often there may seem to be reason for hope that it will escape the dreaded disease. The period at which syphilitic symptoms manifest themselves varies more or less in different cases, from a few hours or days to several months, the exact distal limit being as yet a "moot question." Most writers believe that one year is the outside possible limit at which the first symptoms may appear, while good observers also claim that it has only developed several years after birth. It is more than likely that in these cases there were earlier manifestations which were overlooked, even as is observed in acquired syphilis.

In the vast majority of instances the disease asserts itself soon after birth. Thus of 249 cases collected by Roger (*Union Méd.*, 1865) in 217 syphilis appeared before the end of the third month, and in only 32 did it appear later. In another series of 105 cases, 10 were attacked by the eighth day, 14 more by the fifteenth day, and 21 more by the thirtieth day, a total of 45 within the first month. Other analyses of cases show about the same result, so that in a large proportion of the cases the disease asserts itself between the third and sixth week after birth—in over three-quarters of the cases within the first three months of life. Beyond six months the proportion is exceedingly small, and

yet it is never safe to give an absolutely favorable prognosis as to escape of the child even until after one year old. When the child is born apparently healthy, there is absolutely no means by which it can be determined whether it will or will not exhibit the disease later, and judgment must be suspended, but the case most carefully watched. Sometimes the skin lesions will be the first evidence of the disease, but more commonly symptoms referring to the nutrition or respiration will be the first to show themselves. The child is found to fail in appetite and strength, not to gain in weight, to be restless at night, and to be peevish and irritable. Soon the child's cry is noticed to be harsh and breathing difficult, and the well-known "snuffles" are noticed, with discharge from the nose; the nostrils become obstructed and it is hard for the child to breathe while nursing. The mouth soon becomes sore, the digestion begins to suffer and the child is really sick. With all this the body loses in weight, the skin becomes sallow and wrinkled, the features are drawn, and there is what is known as the "old man" expression. By this time there is usually more or less of an eruption, generally appearing first about the anus or nates, or about the mouth, and also on the palms and soles, which may become very general, and the syphilis is in its full bloom.

It must be stated, however, that the picture here detailed represents the fullest development of the disease, found in aggravated cases, in poor surroundings and unchecked by treatment, and certain points may be wanting in many cases. Under the best circumstances and with intelligent and proper care, all the symptoms may be very much modified, and the syphilitic child saved much of the injury which the poison is capable of inflicting, even as acquired syphilis in the child or adult may exhibit vastly different phases and degrees of danger.

The skin symptoms observed in hereditary syphilis are essentially similar to those seen in the acquired disease, and need not detain us long. Owing, however, to the delicate structure of the infant skin and its high vascularization, they exhibit some peculiarities. The erythematous eruption, or so-called syphilitic roseola, is that most commonly met with, in the form of oval or round pinkish macules, somewhat resembling measles, which may run together, forming reddened areas of considerable size; when they have lasted a while they more or less darken, giving rise to the so-called "coppery hue," but practically this feature is of much less significance than is popularly supposed. About the mouth this form of eruption sometimes lingers as brownish, scaly patches, and the palms and soles may desquamate.

This early erythematous stage may be rather indefinite and brief, and if the disease is unchecked it may pass into or be followed by another eruption of more solid form; this exhibits soft flat papules, large and small, of a dull red color tending to become coppery, and at first smooth on the surface; later there is more or less tendency to scaling, especially on the palms and soles. There is generally no special arrangement of these papules, although at a later period they may form in more or less circular or crescentic patches. Associated with this form of eruption there occur in parts which are moist what are known as condylomata lata or mucous papules. These are seen most characteristically about the anal and genital region, also about the mouth, and even between the fingers.

Owing to moisture and heat, the papules enlarge and become prominent, the surface softens, and may give off a glairy secretion which is exceedingly contagious. It is from this that many of the cases of innocent infection arise. When these papules occur in quantity about the corners of the mouth they give rise to a destruction of tissue which on healing leaves linear, radiating scars which often prove afterward to be a very valuable diagnostic sign. Within the mouth these mucous patches give off a free secretion which is the source of the greatest danger to those associated with the child.

Vesicular and pustular syphilides are comparatively rare in hereditary syphilis, but bullous eruptions are not very uncommon in severe cases. Bullæ are far more apt to appear on the hands and feet, but may be generalized, and may occur very early or at quite a late date in the disease. They always indicate a serious vital impairment, and when present at birth or developing very early, the case almost always ends fatally. Tubercular lesions are rare in the early history of hereditary syphilis, though they have been observed even in the sixth month. Generally they, together with gummatous lesions, belong to a much later cropping-out of the disease—even many years after birth. This brings us to consider briefly some of the late phenomena of hereditary syphilis.

Remembering what has been stated in regard to the very thorough and complete saturation of the system with the poison *in utero*, as evidenced by the many changes found in all the organs, it is not surprising that the hereditarily syphilitic child, if it escapes the lethal perils of early life, should exhibit changes in its various structures due to the action of the poison, and such is unquestionably the case. It is doubtful if one who has suffered much from the early symptoms of the disease, as indicating a severe infection, is ever so completely cured that there are not somewhere effects of the poison in the system. As the papular lesions about the mouth have left scars which remain for life, so infiltrations and alterations in other structures, when they disappear under treatment or spontaneously, leave marks or alterations of structure other than occur in the child whose development has been normal and not interfered with by such a malignant poison. Prominent among these signs of past syphilis stand the changes in the second teeth, to which the name of Mr. Hutchinson of London has been so indissolubly attached. This change in the teeth does not always occur, but when found is certainly a valuable diagnostic aid. It is to be remembered that really only the upper central incisors present truly pathognomonic signs. When characteristically altered, more or less pegged, thickened, and with the curved, horizontal erosion at the end, they are not to be mistaken.

Associated with this change in the teeth there is a tendency to disease in the cornea which Hutchinson has also emphasized as peculiar to hereditary syphilis. This, usually occurring between the ages of three and twenty, results from a more or less diffuse keratitis, which gives rise to a peculiar hazy, ground-glass appearance of the cornea. Happily this condition seems to be getting more rare, owing to good treatment, so that personally I have not met with it for some time, although some years ago I saw it frequently. Ear disease, leading to deafness, also occurs from hereditary syphilis.

Changes in the bones are among the most common

sequelæ of hereditary syphilis, and the flattened forehead with prominence at the sides will often be seen in these cases, in connection with the alterations in the teeth and eyes referred to. The long bones are also very frequently attacked, both in their extremities and shaft. The former, due to an osteochondritis, belongs to the earlier phases of the disease, and by interfering with the nutrition of the bone may produce serious lesions of its structure. Periostitis is commonly of later date, and may cause great deformity and pain; nodes from this cause may often be seen even many years after birth. Dactylitis syphilitica may occur in very young children, or even in early youth; in this there is a general thickening and enlargement of one or more of the phalanges, commonly the proximal, which runs a very slow course, and if injured may break down and ulcerate.

Cutaneous lesions may occur as late manifestations of hereditary syphilis and are mainly tubercular or gummatous. I have seen in a girl 23 years old, exhibiting characteristically pegged and notched teeth and with a well-marked history of hereditary syphilis, ulcerative gummatous disease on the arm, which had always been regarded as lupus, but which yielded rapidly and perfectly to proper specific treatment. Time and space do not permit us to go further into the late manifestations of the disease, such as affections of the nervous system, sexual system, heart, thymus, etc., but it is believed that as research continues it will be found that every portion of the economy is more or less impressed and affected by the profound alterations in nutrition which take place during the active period of the operation of the poison in hereditary syphilis.

We come now to the point of the further transmission of this disease to a succeeding generation. This is a subject which has been hotly discussed, and many have denied its possibility. It would be impossible here to present any of the arguments, but it may be stated that instances are multiplying by reliable observers where such a transmission to a third generation has taken place, and the writer believes that the weight of evidence is now such that it must be accepted as a fact, although such an occurrence is exceedingly rare.

Having now traced the progress of syphilis and its effects from the act of generation to the third generation of transmission, let us very briefly return to the child acutely affected with hereditary syphilis, and consider for a moment its relations to the world.

The already quoted saying of Fournier that "nothing is so dangerous to its surroundings as a syphilitic child," should always be borne in mind in connection with every case of hereditary syphilis. Hundreds and thousands of cases of *innocent syphilis* have had their origin in innocent babes, and too great care can hardly be exercised. Before the danger was fully recognized large epidemics of syphilis have swept through country towns in Europe, while in Russia many villages are said to be almost completely syphilitized, entirely by "family syphilis." I have myself seen most lamentable instances, and not very recently had a grandmother with chancre within the nostril, followed by most severe syphilis with prolonged brain symptoms, who had received the infection from a syphilitic grandchild, which died of the disease.

It is questionable if a child of parents with recent syphilis should ever be wet-nursed. Even if the child exhibit no syphilitic phenomena, there is no certainty

that at some time mucous patches may not develop in the mouth which may infect the nurse. Danger could be avoided only by securing a nurse who was probably immunized by having had syphilis. There would be no danger of adding to the child's syphilis, for it has been pretty conclusively shown that syphilis can not be conveyed by the milk alone.

But even in the artificial feeding and ordinary family care of a syphilitic infant there is danger to those who have not had the disease. Multitudes of cases are on record where the disease has been thus communicated to those around by means of the feeding bottle, from tasting it. I have seen one case where this was believed to be the mode of infection. Time and space forbid our entering further this most interesting field of thought; sufficient to say, the most scrupulous care should be exercised in connection with the hereditarily syphilitic child, that in no way secretions from its lesions should affect others by mediate or immediate contact.

The subject of treatment in connection with hereditary syphilis has several divisions. First we may speak of prophylactic treatment.

The prophylactic treatment relates first, to guarding the prospective child against the dangers threatening from syphilis existing in one or both parents; and, second, to guarding others from the perils incident to the very contagious secretions given forth by the syphilitic child.

Time and space forbid discussion here of the very broad subject of marital syphilis, but it is one which should be very seriously considered by every medical man. The best observers all agree that procreation should not be allowed until after at least two years of active treatment for recent syphilis, and until at least six months have elapsed without treatment and without any manifestation of the disease. When the mother already has active syphilis and has become pregnant, her treatment should be pushed in the most vigorous manner possible. My preference in early syphilis, is for the treatment recommended by Hutchinson, of one-grain tablets of mercury and chalk, given every two hours, to the utmost tolerance of the drug. Eight to ten tablets may be taken daily, and in some cases it is often necessary to double some of the doses, and if necessary to administer opium to prevent purgation. Salivation should not be caused, and to prevent this great care to the mouth may be necessary, with the constant use of chlorate of potash or antiseptic solutions. If there should be intolerance of the stomach, mercurial inunctions should be used, or hypodermic injections of mercury. In somewhat later syphilis, the iodid of potash may also be needed, especially if placental disease is strongly suspected. This very active treatment should be pushed even up to the day of confinement, and as soon thereafter as possible.

Coming now to the prophylactic treatment of the offspring, it may be stated that the hereditarily syphilitic child should be regarded from the first as a dangerous element, even if in apparent good health, for it is never certain how soon syphilitic manifestations may exhibit themselves. It is to be remembered that the coryza may, and usually does, occur before the appearance of skin symptoms, and this secretion from the nasal passages and mouth is intensely virulent, and under proper conditions can give rise to a chancre when least expected. If at all possible, the syphilitic child should be nursed, and by its own mother, as

this affords it the best hope of life and health, as compared with artificial feeding. It should, of course, never be given to a healthy wet-nurse, for, however healthy at the time, mucous lesions may develop at a later period in the mouth, with the almost certain result of a chancre of the breast in the nurse. History is full of records of thousands of instances where this has occurred, and many where veritable epidemics occurred, passing through many individuals by direct or indirect transmission.

If the baby is fed artificially, great care must be exercised that the nursing-bottle and articles connected with feeding, are kept scrupulously clean and away from the possible infection of others. The instances and methods by which brephotrophic syphilis has been communicated would greatly surprise one who has not become familiar with the subject. These can not even be enumerated here, but the list³ amounts to between forty and fifty different categories, relating to almost every possible article of use or means of communication between the syphilitic child and those surrounding it.

The direct constitutional treatment of the hereditarily syphilitic child can be dismissed with few words. When there is strong reason to suspect that the child will develop the disease, a more or less mild treatment should be begun at birth, even before active symptoms manifest themselves, and be continued with judgment until the time of the feared explosion of the disease has passed. With any development of active symptoms the anti-syphilitic treatment should be pushed to all proper bounds.

For the active treatment of the disease no treatment has been devised which is better than inunction, as I believe is universally practiced. The blue ointment, diluted one-half with cold cream, is rubbed over the abdomen and loins, and smeared on a flannel band and worn constantly, fresh ointment being applied once or twice daily, according to the necessities of the case. Grey powder, given every few hours, is also a desirable plan in certain cases, and if there is evidence of intestinal disturbance, the bichlorid of mercury, half a grain to a grain to the pint of water, of which a teaspoonful may be given every few hours. Iodid of potassium is seldom wanted in the early stages.

The greatest care must also be given to the nutrition and general health, and every measure and remedy adopted which will heighten the vitality of the child. Iron is often called for in connection with the mercury, even in very young subjects. Later in the disease, and for the various sequelæ, the treatment is that indicated for acquired syphilis, and need not be detailed here. I may, however, mention that the syrup of the iodid of iron, even pushed in large doses, often yields brilliant results in rebellious cases.

The subject which we have tried to briefly cover is a very large one, and I feel that it has been but imperfectly presented. But if I shall have succeeded in calling attention to any features which may have been forgotten by some, and if a good discussion of the subject shall result, I will be more than satisfied.

Diagnosis of Sinus Thrombosis.—Voss calls attention to the fact that absence of vein sounds on the diseased side is an aid to the diagnosis, only noted in children to date.—*St. P. Med. Woch.*, October 8.

THE MEDICINAL TREATMENT OF CON- GENITAL INFANTILE SYPHILIS.

Presented to the Section on Diseases of Children at the Forty-ninth Annual Meeting of the American Medical Association, held at Denver, Colo., June 7-10, 1898.

BY CHARLES S. SHAW, M.D.

PITTSBURG, PA.

Syphilis is one of that small but happily increasing number of diseases in which special medication can be confidently expected to be followed by certain benefit; its prompt and intelligent treatment, therefore, is of more positive value than is the case in diseases in which the therapy is indefinite, and where remedial agents, especially drugs, are of uncertain action. For clinical purposes the classic division of the disease into three stages is most convenient, though it seems to me the belief of Hutchinson, that syphilis is a true exanthem, running a definite and limited course, is the proper conception of the disease. Under this hypothesis the interval between the initial sore and the appearance of the constitutional symptoms is the period of incubation, the secondary stage is the time of active manifestation of the disease, and the third or tertiary stage is in truth the appearance of sequelæ, and is no more syphilis than nephritis is scarlet fever, or cardiac insufficiency is acute rheumatism. There are many clinical facts corroborating this opinion, which though interesting, are foreign to my subject, and need not be mentioned.

In the treatment of syphilis, the secondary stage, the period of activity of the disease, is the time in which the best results are to be expected. Treatment during the primary stage, even early and complete excision of the initial lesion, has proven unsatisfactory, and, though gratifying results often follow proper medication in the tertiary stage, disappointment is by no means unusual. In the infant we have, as a rule, the secondary stage to treat; the initial lesion never; the tertiary stage rarely, because the child, owing to its slight resisting powers, usually dies of malnutrition before that stage is reached. It is this lack of resistance in the child that makes the treatment of infantile syphilis less uniformly successful than it is in the adult.

In making a prognosis in any case of infantile syphilis my experience has led me to consider as the most important factor, aside from the question of visceral lesions, the nutrition of the child, or rather its capacity to assimilate nourishment. We have all seen children with extensive mucous, cutaneous, and even osseous lesions, who, nursing well and digesting well, will steadily improve, while others, in whom the disease to all appearance is much less virulent, but in whom nutrition is defective, will die. From these observed facts the deduction as to the best method of treatment is obvious—that method which will least disturb nutrition.

The value of mercury in adult syphilis does not admit of question; but in infantile syphilis it is unique, it is the only drug. The iodids, arsenic and iron, so valuable in the treatment of the sequelæ in the adult, have little place with infants, because this stage is seldom reached. While it is true the child may need a tonic, it is a general need and not a specific one. Mercury in some form is a *sine qua non*. It is a question, therefore, of method of administration and choice of preparation.

Four ways of giving mercury are in vogue: by the

mouth, by hypodermic injection, by vaporization, and by cutaneous inunction. The advantages of giving by the mouth are convenience, exactness of dose and control of effects, the disadvantages are slowness of action and the likelihood of digestive disturbances. The advantages of hypodermic injection are rapidity of action, certainty of action and exactness of dose; the disadvantages are pain, which is often severe, and the possibility of abscess. The advantages of the vapor bath are rapidity and certainty of action; the disadvantages are inconvenience, the need of special appliances, and inability to always control its action, severe mercurial ptialism occasionally occurring. The advantages of inunction are certainty and rapidity of action and control of effect; the disadvantages are, uncleanliness, inconvenience and the possibility of cutaneous irritation.

The first and usual method—by the mouth—is contraindicated in infants by the digestive disturbances that so frequently follow the internal use of mercury in them. In adults this is not usually a serious matter, but in view of the supreme importance of preserving and increasing the nutrition of the syphilitic babe, and the danger of digestive derangements, this disadvantage amounts in many cases to an interdiction. The hypodermic method in infants is objectionable because of the pain and of the possible abscess that attend its use; if by any other method we can secure its virtues, certainty of action and control, we may dismiss it as inapplicable. The troublesomeness of the vapor bath is greater in infants than it is in adults, and the danger of mercurial poisoning is certainly not less; it may therefore be considered as of doubtful utility. There remains the fourth method—that of cutaneous inunction. The advantages—certainty and rapidity of action and control—are at least as evident in infants as in older patients, and the disadvantages of uncleanliness and inconvenience disappear altogether in infancy. The question of cleanliness is an individual one, and as the infant has no sense of personal cleanliness, the objection, so forcible with the adult, does not obtain. The question of convenience is also an individual one; the method is certainly troublesome to the adult, but it is not so to the infant nor its attendants. The liability to cutaneous irritation can be completely removed by a little care. In my opinion the evidence is clearly in favor of inunction.

The eligible preparations are the unguentum hydrargyrum of the pharmacopeia and the official 10 per cent. oleate of mercury. These should be diluted with an equal quantity of lanolin, lard or vaselin and they will rarely irritate the skin. The method of administration is very simple; spread about one dram of the ointment on a small piece of cotton or flannel cloth and lay it on the child's abdomen, covering it with the binder; or, more simple still, spread it on that edge of the binder that is first applied to the child's body; every second day bathe the child and reapply the ointment. The warmth of the child's body, the gentle friction produced by its movements, and the activity of its cutaneous circulation all contribute to the speedy absorption of the medicament. Under certain urgent conditions, when it is necessary to quickly and powerfully impress the system, it may be advisable to have temporary recourse to one of the other methods to aid the inunction, but the systematic, persistent treatment may be reduced to this aphorism: There are two ways of treating infantile

syphilis, a right way and a wrong way; the right way is by mercurial inunction, the wrong way is any other way.

THE DEBILITY OF ADOLESCENCE.

Presented to the Section on Diseases of Children, at the Forty-ninth Annual Meeting of the American Medical Association, held at Denver, Colo., June 7-10, 1898.

BY LOUIS FAUGÈRES BISHOP, M.D.
NEW YORK CITY.

It has always been a puzzle to me to know just when the specialist on diseases of children gave up his case to the specialist on older people, and just when the specialist on older people gave up his patients to the specialist on old age. This suggests the existence of transition periods. There might well be study devoted to the period during which the child is passing from childhood to maturity. Of course, the child grows steadily from birth to manhood, but there is a period during the latter part of this time to which the name of adolescence is given, a period during which the youth is subject to particular departures from health.

During this period, when the active forces of early development have begun to wane and the solidification of maturity has not yet taken place, the organs are especially susceptible to damage from whatever causes may be active. Thus in early youth the poison of tobacco is badly borne, and functional derangement of the heart is a frequent result from doses of nicotine that at maturity have no such effect. In the same way the acute infectious diseases have a greater liability to involve the kidneys. The tendency to defective action of the blood-forming organs is the cause of the extreme frequency of simple anemia between the ages of 16 and 25. During this period also acute gastric attacks are frequent. Temporary nervous affections, such as hysteria and melancholia are met with in individuals, who during the rest of their life are free from these disorders. Headaches of a persistent and troublesome type, not traceable to any other cause than debility, constitute a troublesome condition. The importance of special attention to these symptoms at this period of life is that their true bearing shall be understood so that a just prognosis may lead to patient management and the final development of the youth into a sound adult. It frequently happens that the debility of adolescence is most marked about the time the boy or the girl would pass from school to college. In some instances this breakdown of the vital forces is so marked that it is advisable to allow an interval in the educational course of, perhaps, a year, devoted to travel or an out-door occupation. Too frequently the boy goes to college and his health falls a victim to irregular hours and mild dissipations that his stronger classmates are easily able to bear. This condition, to which we have given a name, is more difficult to manage on account of its indefiniteness. If we can convict a patient of nephritis, or gastritis, or incipient tuberculosis, it is easy to obtain a hearing for our counsel, but to call it debility is not always enough for the layman.

Then there are certain cases, the care of which is incumbent upon physicians, that are not so easy to define as are particular diseases. One of these conditions is a certain laxness of fiber of the body as a whole, but which manifests itself more especially in certain directions. It is specially common in young persons who have grown rapidly in height and

in bulk but whose organs have apparently not increased in power in a ratio proportionate to the size of the body. These young persons are prone to suffer from anemia, cardiac insufficiency, gastric disturbances and a mild neurasthenia. On account of their size and muscle they are tempted to take part in athletic contests, much to the injury of the poorly developed heart. They acquire by exercise enormous appetites, that when gratified overtax the powers of the stomach and cause dyspepsia. The bad heart action, the disturbed digestion, create a vicious combination when combined with anemia, and may give rise to disturbance of other organs. There may be albuminuria and even edema. This may or may not indicate a real nephritis. So we have the picture of a man, or rather a boy the size of a man, who has outspread in his physical growth the capacity of his organs, and suffers from a deficiency of the blood-making, the blood-circulating, and the food-digesting organs with an accompanying neurasthenia. The question of the management of these cases is a difficult one. Should such a constitution be hardened and developed through work, or should the organs simply be allowed a chance to increase in power by rest? Should the mind be taken out of itself by the forced application of school and college, or should it be diverted by travel or amusement? Then the question of the administration of drugs arises. It would seem that no specific rules are possible. Each case must be managed on its merits. The important beginning is to recognize the condition, and not to write the boy down as a dyspeptic, a case of cardiac disease proper, a case of nephritis, or even a neurasthenic, though any or all of these conditions may exist in their incipency and be possible under bad management. In the average case it is better not to take radical measures, such as removal from college, but rather to protect the weak organs by preventing over-exertion in athletic contests, over-study and depressing surroundings. The tendency to hypochondriasis is great, so that it is important that the boy should be treated as little as possible as an invalid.

The albuminuria of adolescence has recently attracted my attention, especially because of its observation in a particularly interesting case. This has led to the consideration of this organic debility, observed quite frequently in boys and girls just previous to the period when they reach maturity. Thus, often, a boy who during his entire early life has been well nourished and strong, during the period of rapid growth, becomes anemic and emaciated. With this, there is an inability of the digestive organs to properly carry on their work. There is apt to be trouble with the eyes, headache, feebleness of the circulation, morbid nervous manifestations, and a general condition of debility. We can not say these cases are of dyspepsia, neurasthenia or anemia, because they are all three, and yet they are none of these. It would seem that rapid growth, under unfavorable conditions, had for the time being exhausted the organs and produced debility. When this debility has been removed the suspicions of organic disease are likewise dissipated. Like acne, showing the inability of the sebaceous follicles to properly empty themselves, it will last until the tone of the whole system recovers from the strain of adolescence.

In the management of adolescence are to be considered the counter-claims of a system of hardening by exposure and hardship and a system of coddling

to conserve bodily forces. It is indeed an important question. The Spartan régime that develops only what can be developed under a rigorous education, and destroys what can not be perfectly developed, is out of tune with modern civilization.

On the other hand, there can be no doubt of the quality of the fiber that is developed in youth by a severe system of training. In educational institutions classification is the safeguard. The pupils should be distributed in small groups so that the ambition of each should be stimulated by a proper rivalry, but not annihilated by oppression. Here the physician should insist that any who suffer from the debility of adolescence should be protected from the injury of an injudicious system of education. Let the mental training, if possible, be deferred for a time while the child or youth is allowed to relapse more into a state of nature. Happy is it for such a patient if country life and country pursuits are available. The administration of drugs will consist only of the quite persistent use of cod liver oil and iron and the occasional stimulation of the functions of the alimentary canal. The conditions of life are to be readjusted so that a normal and healthy manhood may finally be reached by the youth whose adolescence has been characterized by this peculiar lack of vitality.

During this period of life young persons often suffer from what almost amounts to cruelty on the part of their superiors, who do not appreciate that there is a real underlying debility, not only of actual physical endurance, but of nervous power. I have no doubt that many of the robust older people, who tell us that when they were young they were threatened with consumption, and were sent away for a year, were in the hands of some wise old practitioner, who appreciating their condition, used a little justifiable exaggeration to obtain obedience to his advice.

A great danger is that a boy of this character may aggravate his condition by the use of tobacco, to which he would be unusually susceptible on account of the already feeble heart action. Can such a boy lead a pleasant outdoor existence with moderate interesting occupation, removed from the worry and burden of school life, in course of a few years the heart, stomach, kidneys and nerves will acquire development and efficiency equal to the bulk and demands of the system at large, so that the patient may in every respect be a normal individual. These conditions are worth careful consideration because the danger of supposing wrongly that we have to deal with chronic organic disease is great. On the other hand, we must not confound the symptoms of this condition with very similar manifestations due to, for instance, a real nephritis following the exanthemata.

So it is important to recognize the general physical conditions incident to the several periods of life. Each has its special features. It is convenient and advantageous to separate medical work into divisions for study. It is the privilege of the general practitioner to meet now with one group of students and now with another. All workers in diseases of children must of necessity be general practitioners in the broadest sense, so that in this section a study of the transition period will not be out of place.

30 West Thirty-Sixth Street.

DISCUSSION.

Dr. SLAGLE of Minneapolis—We all see cases of those growing too fast and those frequently who are pushed too fast, those whose muscular system has grown too fast for the inter-

nal organs. The essayist confined it, I noticed, entirely to the masculine sex but it is perhaps as applicable to girls in many instances. Chlorosis is very frequent in this class of patients in our part of the country. The caution the essayist gives about pushing those children or branding them as indolent is very good.

Dr. R. B. GILBERT, Louisville—The patent nostrums we see advertised, which in many instances are composed of alcohol or opium in disguise, are frequently used. These cases are often treated too lightly by the family physician. The symptoms are too indefinite, so that the hasty answers he gets from the doctors he applies to, are unsatisfactory. Then it is he falls a victim to the patent medicines, to his great injury. It is a subject we should consider carefully and we should pay more attention to that class of adolescents, take them out of school, take them off cigarettes and tobacco, of course, and send them to the country. I remember a young man who began the study of medicine, against my advice, at 18 years of age. After a year he got into such a condition that he abandoned the practice of medicine and went to Colorado and hired himself out as a herder of sheep. He came back to our country a healthy and ruddy individual. Possibly the celebrated climate here had something to do with it, but I think it was more the rough and tumble life he led and the rough food he had to eat. At home he had been fed on all the delicacies the markets could afford. Give the boy encouragement, let him know he has the elements of health in him and put him out where he can get a move on him. It is not often the case that they get into the army, but in the volunteer service I remember several such individuals. One, a cousin of mine, was just that sort of an individual, and camp life, his mother thought, would be the death of him in a month. She sought his release but the officers would not relieve him. After six months he was rosy and fat on hard tack and bacon.

Dr. McCONNEL—In my experience in all these cases there is a cause, and in my experience the cause has been in the stomach. These young men have not a so-called dyspepsia, but they have mal- or non-assimilation. While they have no appetite, they are fed on all the delicacies of the season, their appetite is pampered and as a consequence they eat more than they can digest. If their appetite is carefully cared for and if they are impressed that stuffing is not nourishing, they soon will get an appetite and assimilate the food. When a boy gets in this condition the first thing the physician tells the parents is to take the child out of school. Nothing flatters the parents more than to tell them that their children are studying too hard. Oh, they love to hear that! Nine times out of ten they are not studying at all. I tell you, gentlemen, it is not over-study: it is under-play. It is wrong and a great injury to these cases to take them out of school.

Dr. H. W. SCAIFE, Chicago—The last speaker but one gave us an instance of a boy who was over-growing and was sent out west and followed the occupation of a cowboy. That coincided with what I said, that they should have pure air and pure eating and should change their diet to a different line. He mentioned an instance where a youth grows too fast, the muscles outweighing the conditions of the brain. We know there are some people who keep on growing until the time that they die. Some plants we know will grow forever. The oak tree will grow a thousand years. The reason is that they have that in them which is trying to balance the formative power or the building up of the organism, and life is in no hurry to leave them. I believe that what has been said in the way of remarks on the second paper would apply very well to mine.

Dr. EDWIN ROSENTHAL, Philadelphia—The question of adolescence has been brought forcibly to my mind in the cases of young ladies suffering from chlorosis or rheumatism or chorea, and the only way we can cure them is to take them away entirely from their usual work and place them among the sav-

ages, and in that way you can build up the nervous system so you can cure them of the nervous diseases. If you take the half-grown boys who have ear-aches and who pay attention to their faces to press out the little comedones and imagine they are ill, it is just as important that they should be treated as if they were affected with typhoid fever. You will find each of these boys has a specific. They have a book in their pocket which tells all about the hundred and one things they have. It is true the stomach is the cause of a great deal of this disease, for if they get a little wind in the colon, away they go into hysteria. The only way you can cure them is to bring them down to nature, send them out to farms or out here or to the army. But with medicines the patients grow up to be invalids, the kinds the books in the drug-stores tell us about.

Dr. LOUIS FAUGÈRES BISHOP, New York City—I think the object of the paper has been fulfilled. I drew attention to this condition. I did not mean to neglect these girls by using "he" but I meant that to cover the whole race.

TETANY IN INFANCY; WITH A REPORT OF SIX CASES.

Presented to the Section on Diseases of Children, at the Forty-ninth Annual Meeting of the American Medical Association, held at Denver, Colo., June 7-10, 1898.

BY JOHN LOVETT MORSE, A.M., M.D.

Physician to Out-Patients at the City Hospital and at the Infants' Hospital, Boston; Assistant in Clinical Medicine, Harvard Medical School.
BOSTON, MASS.

Very great differences of opinion exist with regard to what constitutes tetany, as well as to the frequency of its occurrence and its etiology and pathology.

It is generally accepted that the most characteristic symptom of tetany is muscular rigidity, this rigidity occurring as intermittent paroxysmal contractures. The duration and intensity of the contractures vary, in some cases being long and remittent, in others fleeting and occurring at long intervals. The extent of the contractures also varies within wide limits, the seat par excellence, however, being in the muscles of the arms, especially of the fore-arms. The positions assumed by the hands and feet during these contractures are very characteristic. The fingers are flexed at the metacarpo-phalangeal joints, while the phalanges are extended. The thumb is strongly adducted in the extended position. The wrist is acutely flexed and the hand turned to the ulnar side. The elbow- and shoulder-joints are not involved in the milder cases. The feet are strongly extended, sometimes in the position of pure equinus, but more often in that of equino-varus. The first phalanges of the toes are strongly flexed, the others extended. The knee- and hip-joints are usually free. Opisthotonos is not very uncommon in the severe cases. Associated with the contractures are other symptoms, some or all of which are present in every case. These are: Increased electric excitability of both nerve and muscle to faradism and galvanism, with changes in the qualitative reaction to galvanism. This is often known as Erb's symptom and is probably the most constant. Increased mechanical excitability of both nerve and muscle. Special examples of this are the occurrence of characteristic contractures as the result of pressure on the large nerve trunks and arteries, "Trousseau's symptom," and spasm of the facial muscles when the skin over the trunk of the facial nerve is irritated or the nerve is struck a sharp blow, "Chvostek's symptom" or the "facialis phenomenon." Laryngospasm. Convulsions. Sensory disturbances, including pain on

motion and during spasms, as well as many others impossible to determine in infants. Vasomotor and trophic disturbances, the most characteristic being edema of the wrists and ankles. Fever, which is inconstant and intermittent. The intelligence is always unimpaired, even during the paroxysmal contractures.

All agree that the presence of the peculiar paroxysmal contractures justifies the diagnosis of tetany. There is great difference of opinion, however, as to whether the presence of one or more of the other symptoms without contractures justifies the diagnosis. It is to this condition that the term "latent tetany" is applied. Even here, however, there is no consensus of opinion, some apparently limiting the term to the condition in which irritation of the muscle or nerve brings on contractures which are otherwise absent, while others consider the presence of even one symptom as pathognomonic and sufficient for the diagnosis. As a rule, those who recognize the existence of latent tetany consider it the same as tetany, differing from the latter only in degree. If these symptoms are to be considered as pathognomonic and sufficient for the diagnosis of tetany, whether the characteristic contractures are present or not, they should be always present where there are contractures and should never occur in other conditions. Trousseau's symptom and the facial phenomenon are sometimes absent, and often only temporarily present when there are typical contractures. Moreover, Trousseau's symptom is often met with in hysteria, while the facial phenomenon is found in many other conditions, as epilepsy, hysteria, phthisis and neurasthenia. Laryngospasm is frequent in tetany, but not constant, and is often seen in children who have no other symptoms of tetany. Convulsions and disturbances of sensation, as well as vasomotor and trophic disturbances, occur in many other diseases. It is evident, therefore, that these three symptoms—laryngospasm, Trousseau's symptom and the facial phenomenon—are not constant in cases which show the typical contractures of tetany, and that they occur in many conditions in which there is no question of tetany. Hence they can not be considered as pathognomonic of tetany, and do not, either singly or in combination, afford sufficient ground for the diagnosis either of tetany or latent tetany. They must be regarded merely as particular instances of increased mechanical or reflex excitability which may be the result of a very great variety of causes and pathologic conditions. The only pathognomonic symptom of tetany, therefore, is spontaneous, intermittent, paroxysmal muscular contracture. The term "tetany" should be applied only to those cases in which this symptom is present, and no cases of increased reflex excitability in which this symptom does not occur should be regarded as examples of the disease. The term "latent tetany," is therefore a misnomer and should be dropped.

ETIOLOGY.

Numerous theories as to the etiology of tetany have been advanced, and have found vigorous defenders and opponents. The question is still unsettled, however, probably partly on account of the differences of opinion as to what constitutes tetany, and partly on account of the inherent difficulties of the subject. The theory of the older authors that it is of rheumatic origin has long been given up. The position that it is merely a manifestation of hysteria must also be regarded as untenable. The theory that it is cerebral in origin was founded on an erroneous conception

of the disease, and is no longer accepted. The theory that it is a variety of acute anterior poliomyelitis can not easily be set aside, however, as certain quite definite lesions have been found in the anterior horns. As the cases of tetany which do not die of some intercurrent disease nearly always recover, these lesions must, as a rule, be transitory. They may very probably be frequently due to the action of toxic substances in the circulation, the result of diseased conditions elsewhere.

The most ardent and extreme advocate of the rachitic theory is undoubtedly Kassowitz. His line of argument is somewhat as follows: Craniotabes is a lesion of rickets. Craniotabes may be represented only by meningeal hyperemia, and hence be incapable of demonstration. Laryngospasm is due to craniotabes. Laryngospasm is a symptom of rickets. Other symptoms of increased neuro-muscular excitability are seen in rickets. They are of the same nature as laryngospasm and hence due to the same cause. Laryngospasm and other nervous manifestations are symptoms of tetany; in fact, they are tetany. Hence tetany is a symptom of rickets.

There are many obvious objections to this reasoning. It is not proven that craniotabes is the cause of laryngospasm, or that meningeal hyperemia produces the same results as craniotabes. Moreover, laryngospasm occurs in tetany when there is no evidence of rickets, in rickets when there are no other evidences of tetany, and alone when there are no evidences of either tetany or rickets.

Although not agreeing with the extreme views of Kassowitz, most of the German and Austrian authorities have accepted the rachitic theory in a more or less modified form. Some of the arguments in favor of this view are, that almost all cases of tetany show evidences of rickets, that they are both more frequent in winter, and that they occur in children of the same age. Some of the arguments against it are, that very many cases of other diseases than tetany show evidences of rickets, that the symptoms of increased neuro-muscular excitability, with the exception of laryngospasm, are rare among rachitics, and that tetany is more likely to occur in mild than in severe cases of rickets. The fact that rickets is common all the year round, although much more so in the winter, while tetany very rarely occurs in the summer, would seem to point to some common cause for both conditions which is active only in the winter. This cause is most probably the indoor life of the winter, with its lack of sunlight and oxygen and its exposure to noxious vapors. These furnish the opportunity for the formation of respiratory toxins which may produce changes in the circulation that lead to malnutrition of various tissues with subsequent symptoms.

Several theories locating the origin of tetany in the gastro-intestinal canal have been advanced. These have received their main support from the French authorities. The dehydration and reflex theories need be mentioned only to be set aside. That of auto-intoxication, however, is worthy of careful consideration. The friends of this theory say that tetany is almost always associated with diarrhea or other digestive disturbances. They say that the reason that all children suffering from indigestion do not have tetany is that some peculiar chemic combination is necessary, or because their nervous system is insusceptible. When tetany occurs in infants who present no symptoms of indigestion, they assume that the nervous

system is easily affected, or that this peculiar chemic combination may be produced without causing other symptoms. They also state that when the digestive disturbances are relieved the tetany ceases. They attribute the frequency of tetany in rachitis to the gastro-enteric disturbances of this disease. The opponents of this theory say that gastro-enteric disorders are very common and tetany very rare; that digestive disturbances are more common in summer and tetany in winter; and that the only basis for the assumption of peculiar susceptibility or special chemic combinations is in the imaginations of the originators.

The most recent, and perhaps the most plausible, theory assumes that there is no single pathologic cause for tetany, but that, like epilepsy, it may arise from many causes. Like epilepsy, too, it must be regarded merely as a nosologic entity, and not as a definite disease. In improper hygienic surroundings, in rickets, in gastro-intestinal disorders, in acute disease, and in various intoxications are present conditions capable of causing the formation of various toxic substances. The action of all these poisonous substances may show itself by a special modification, rather functional than organic, of the central or peripheral nervous system. The various lesions of the nervous system found in tetany are not inconsistent with this conception.

MORBID ANATOMY.

The lesions which have been found in the nervous system in tetany are very variable. Tonnellé, Blondeau, Grisolles, Trousseau and Bouchut have found hyperemia of various portions of the brain and cord and their meninges; Weiss, Bonome, Cervesato and Sarbo various degrees of poliomyelitis of the cervical enlargement; Stasse, Niemayer and Schultze peripheral neuritis; and Loos, Berger and others no lesions. The most characteristic lesions, however, are probably those in the cells of the anterior horns in the cervical enlargement. These vary in degree from hyperemia and swelling to atrophy and sclerosis, the severity of the process probably depending on the duration and intensity of the disease. It is probable that certain lesions in this region are present in all cases, but that in recent ones they are too superficial to be recognized. Whether they are primary here or secondary to an ascending neuritis is at present entirely undetermined. As they have not been found constantly, however, further verification is necessary before they can be accepted as the essential lesions of the disease. Nevertheless, they do correspond more closely to the symptoms of the disease than any other lesions which have been described, and seem at any rate to afford a fairly satisfactory explanation for them.

FREQUENCY.

The frequency of tetany must naturally depend on the definition of the disease which is accepted. If the presence of symptoms of increased neuro-muscular excitability is considered as evidence of latent tetany, and latent tetany is classed as tetany, the disease will be frequently encountered. If, however, only those cases in which the typical paroxysmal contractures are present are regarded as tetany it will be seen much less often. This difference in classification undoubtedly explains to a great extent the much greater frequency of the disease in Germany and Austria than in France and Italy. It does not

entirely account for the discrepancy, however, and there is probably but little doubt that tetany, even in the strict interpretation of the term, is much more common in the first-named countries. It is still less common in this country, being, indeed, something of a rarity. Griffith, in addition to five cases of his own, was able to find but seventy-two cases reported in American literature up to 1894, although he included in his list a number of cases of muscular spasm, which, strictly speaking can not be accepted as cases of tetany. In a careful review of American medical literature from Jan. 1, 1894, to Jan. 1, 1898, I am able to find but thirteen additional cases. They are, in brief, as follows:

1. Lewi: Nine months. Constant, typic spasm in hands. Arms and legs painful. One convulsion. Spasm became remittent, then ceased. Duration, three weeks. Neurotic family history. Rachitic. No craniotabes. No gastro-intestinal disturbances.

2. Lewi: Eight months. Typic, intermittent spasms in hands and feet, lasting hours or days. Hands and feet tender and painful. Increased electric reaction. Duration, six weeks. Recurrent attack two months later with death in convulsion. An older child had had disease. Rachitic. No craniotabes. Gastro-intestinal disturbance always. Constipation during attack.

3. Lewi: Eight months. Typic, continuous spasm in hands and feet. Hands and feet swollen, tender and painful. Increased electric reaction. Duration, two weeks. Rachitic. No craniotabes. Vomiting. Constipation.

4. Lewi: Thirteen months. Remittent spasm in hands and feet, most in hands. Hands and feet swollen, tender and painful. Laryngismus stridulus. Duration, two weeks. An older child had had disease. Markedly rachitic. No craniotabes. Vomiting. Constipation.

5. Crandall: Six months. Began with peculiar attacks of staring. In a month well-marked and typic paroxysms, involving neck and all extremities, lasting one and a half to two hours. Five to eight attacks in twenty-four hours. No laryngismus stridulus. Duration, eight weeks. Moderately rachitic. No craniotabes. Poor breast-feeding. Diarrhea, later constipation. Phimosis. Correction of phimosis had no effect. Complete recovery in eleven days after correction of diet and relief of constipation.

6. Crandall: Eleven months. Twelve to twenty-four attacks of laryngismus stridulus and convulsions in twenty-four hours. Duration, two minutes. Spasms fairly typic. Duration, three weeks. Markedly rachitic. No craniotabes. Breast and general diet. Vomiting. Alternate diarrhea and constipation. Recovery in two days after correction of diet and cathartic.

7. Preston: Three and a half years. Typic spasms in arms, less so in legs, lasting a few minutes; intervals of months or ten to fifteen in twenty-four hours. No pain. Trousseau's symptom present. Began at one year. Duration unknown.

8. Krause: Six months. Typic paroxysms; continuous for two weeks at height of attack. Much pain. Swelling of face and extremities. Trousseau's symptom present. Duration, five weeks. No note as to rickets. Artificial food. Constipation, then diarrhea. Dentition.

9. Krause: Eighteen months. Mild attacks, lasting a few minutes, at intervals of half an hour to two hours. Duration, one week. No note as to rachitis. Vomiting. Diarrhea. Bronchitis.

10. Krause: Thirteen months. Mild attacks, lasting five to ten minutes, several times, daily. Duration, sixteen days. No note as to rachitis. Gastro-intestinal disturbance. Bronchitis.

11. Krause: Nine months. Paroxysms, involving hands and legs. Duration, three weeks. No note as to rachitis. Bronchitis.

12. Krause: Eleven months. Remittent paroxysms; most severe in arms. Duration, two weeks. No note as to rachitis. Severe gastro-intestinal disturbance. Dentition. Bronchitis.

13. Carpenter: Eleven months. Tonic spasms. Laryngismus stridulus. Recovery, slow. Mild recurrence for several years. No note as to rachitis. Followed purulent effusion in shoulder-joint after scarlet fever.

A case reported by Miles as tetany, and another by Carpenter, are probably cases of tetanus. In another, reported by Carpenter, the diagnosis was based entirely on laryngismus stridulus, and, therefore, can not be accepted.

The disease is certainly a very unusual one in Boston, as is shown by the following statistics from the Medical Out-Patient Department of the Infants' Hospital, during the last two years. The great majority of the patients treated there are infants under two years of age, belonging to the poorest classes. Both their age and hygienic surroundings would seem likely, therefore, to render them especially favorable subjects for the development of both rickets and tetany. Seventy-one hundred and fourteen cases of disease were treated during the years 1896 and 1897, and among them was one case of tetany. One hundred and ninety-six were classified as rickets. This number, however, comprises only those cases in which rachitis was the condition demanding treatment, and does not include the far greater number of cases in which rickets was present as a complication. The one case of tetany, which is reported in full below, showed but few evidences of rickets. It would seem from these figures, therefore, that rachitis is not a factor of great importance in the etiology of tetany. I have, during the last five years, seen six cases of tetany in infants. Three were mild and three severe. The histories of these are as follows:

Case 1.—Annie P., four months old; was seen at the Massachusetts Charitable Eye and Ear Infirmary on account of a suspicious eruption. The mastoid disease, for which an operation had been performed some days before, was progressing favorably. Nothing was known as to her history, and the contractures had not been noted. There was slight diarrhea and the temperature was moderately elevated. Handling was somewhat painful. There were frequent, short, typic paroxysmal contractures of the hands and arms. No laryngospasm; facial phenomena absent; Trousseau's symptom easily elicited; knee jerks exaggerated. There were no evidences of rickets. She unfortunately soon passed out of observation, and nothing is known as to the further progress of the case.

Case 2.—Gladys R., colored, four months old, was brought to the Infants' Hospital chiefly because she did not gain weight. She had always been feeble, and was said to weigh less than at birth. She had been fed on a varied collection of patent "foods," the mixture at the time being one of Mellins' Food and boiled milk. She had all of this mixture which she would take at any time. There was no vomiting, some abdominal pain, and a moderate diarrhea. She had "spasms" frequently, in which she "wriggled and clenched her hands." No laryngospasm. She was poorly developed, but fairly nourished. There was no evidence of rickets. During the examination there were frequent short, intermittent, typic contractures in the arms and hands. There was apparently no pain, either on handling or during the paroxysms. The facial phenomenon could not be obtained, but Trousseau's symptom was easily elicited. She was given a carefully modified milk, but no drugs. When seen, eight days later, she had gained ten ounces, and the gastro-intestinal symptoms had diminished greatly. There had been no spasms for some days. Trousseau's symptom, however, was easily developed. She was then lost sight of, and nothing is known as to the final outcome of the case.

Case 3.—Rebecca B., ten months old, was brought to the Infants' Hospital, May 6. Since the first of January she had had one or more "spasms" a day, lasting from a few seconds to five minutes. They also sometimes occurred during sleep. In these "spasms" the upper part of the body stiffened, the arms were flexed at the elbows, the thumb contracted into the palm, and she "got black in the face." For the same length of time she had had frequent attacks of noisy breathing. An older child had had a similar trouble, lasting a month at one time. She was fed on breast milk and on a mixture of cow's milk and water. She seldom vomited, and the dejections were normal, except for an occasional curd. Her surroundings were very good for a child of the poorer classes. She was well developed and nourished. Color good. Skin normal. Anterior fontanelle, six c.c. by eight c.c. No craniotabes. Two teeth. Spine normal. Heart and lungs normal. A considerable rosary. Flaring of lower chest. Abdomen large. Spleen palpable. Epiphysees at wrists enlarged. During the examination she had a typic contracture, involving the arms only, lasting about half a minute. She also had several attacks of laryngospasm. The facial phenomenon was easily elicited, but Trousseau's

symptom could not be produced. The reflexes were normal. She was put on a carefully modified milk in addition to the breast, and given small doses of bromid. The spasms ceased on the 10th and the laryngismus on the 23d. The facial phenomenon was present on the 10th, but had disappeared on the 13th. No new symptoms developed.

Case 4.—James C., six months old, was seen in consultation with Dr. J. L. Ames, Jan. 25, 1898. He was a large, strong baby at birth, but was completely upset by improper feeding during the first six weeks. From that time on his digestion was feeble, although he was carefully and correctly fed. He did not gain normally, and vomited from time to time. The stools, however, were normal. His care and surroundings were irreproachable. On the 19th day he began to vomit again, but his dejections remained normal. He cried much, and seemed to be in pain. His temperature ranged in the neighborhood of 100 degrees. Slight "clenching of the hands,"—first noted on the 20th—gradually increased. He had a mild "spasm" on the 23d. He was cutting several incisor teeth. The urine was diminished in amount. He was fairly developed and nourished. Skin in good condition; rather pale. Fontanelle level—not tense. One tooth; gum distended by another. Slight stomatitis. No rosary. Heart, lungs and abdomen normal. Moderate umbilical hernia. Phimosi. No rigidity of neck, but tendency to hold head backward. Remittent contractures of hands and feet, apparently not attended by pain. Extended thumbs strongly adducted into palms. Little and ring fingers flexed at metacarpo-phalangeal joint, extended at phalangeal; other fingers firmly flexed. Slight flexion at wrists. Elbow and shoulder joints free. Feet in perfectly typical position. Toes sharply flexed at metatarso phalangeal joint, extended at phalangeal. Foot much arched and extended. Knees and hips flexed. Reduction of spasm not painful. Facial phenomenon doubtful. Trousseau's symptom easily elicited. Knee-jerks lively.

He was given a different modification of milk, calomel, salol and bromid. The further treatment was on these same lines. He had numerous spasms during the next few days and the paroxysmal contractures increased in severity. Under careful feeding all the symptoms of indigestion disappeared during the next month, but there was no gain in weight. After the first week the contractures diminished rapidly in frequency and severity and were entirely gone in a month.

Case 5.—John W., four months old, was brought to the City Hospital, Oct. 21, 1897. There was no specific history, and the other children were in every way normal. He was born at full term, after a rapid, normal, vertex labor. Convulsions are said to have begun on the day of his birth, and to have continued until some time in July. The mother also states that she noticed contraction of the fingers after the first convulsion, and that it has persisted since. I saw him at the Infants' Hospital in July, however, but noticed no contractures. I sent him to the Summer Hospital at Rainsford Island, with the diagnosis of "starvation." He remained there for some weeks, but no contractures were noted.

He was fed on condensed milk previous to his admission to Rainsford, and on modified milk during his stay there. He was then given Mellins' Food, which he was taking when seen. He had been vomiting for some weeks. The bowels moved two or three times a day, the dejections being large, yellowish-white and undigested. He slept but little and cried constantly. "The whole body was constantly rigid, the spasm not even relaxing in sleep." Motion was painful.

Poorly developed and emaciated; skin dry; fontanelle level; snuffles; no teeth; mouth normal; tendency to laryngospasm when crying; unable to hold up head when sitting; when lying, head held backward stiffly, but spasm can be overcome; facial phenomenon not obtained; heart and lungs normal; no rosary; abdomen large and tense; slight umbilical hernia; no enlargement of liver or spleen; phimosi; no glandular enlargement; arms held rigidly flexed at the elbow; shoulders also somewhat rigid; wrists slightly flexed, hands in pronation; extended thumbs very strongly adducted across the palms; fingers flexed at metacarpo-phalangeal and first phalangeal joints, extended at the second. This spasm varied in intensity, but was never voluntarily relaxed. It could be almost entirely overcome, but only with the causation of considerable pain. Trousseau's symptom was not determined because of the constant spasm. There was a tendency to hold the legs crossed, and at times the knees were flexed and the feet extended. The spasm was always very slight, however, and was easily overcome; knee-jerks exaggerated; electric reactions and sensation not determined.

Warm baths and light rubbing were advised. He was put on a properly modified milk and given small doses of bromid of potassium. Improvement in the digestive symptoms was

almost immediate and was soon followed by improvement in the nervous symptoms. By November 7 the spasms were intermittent, occurring only at intervals, and the arms and legs were used a little voluntarily. Trousseau's symptom was easily elicited. By November 27 the spasms were very infrequent and of slight intensity and all motions were free. All trace of spasm disappeared some weeks later and Trousseau's symptom could not be elicited. There has been no recurrence of the symptoms.

JOHN W.

Case 6.—Sherry M., 10½ months old, was seen at the Infants' Hospital June 1, 1897.

Family history: No tuberculosis nor syphilis; father and mother each 29 years of age and well.

First child—Instrumental; nursed; always well.

Second child—Instrumental; nursed; always well.

Third child—Instrumental; nursed only; well up to 11 months, when had an attack of vomiting and diarrhea and began to stiffen. Vomiting, constipation and wasting continued and stiffness increased and continued up to death at 18 months. Had no food but breast and beef-juice.

Fourth child—Instrumental; nursed only; well up to 7 months, when had a cough and cold followed by vomiting, constipation, wasting and gradually increasing stiffness ending in death at 11 months. Food was breast, cream and orange juice.

Fifth child. The patient. Normal vertex labor; was well up to 7 months, when it was noted that she was not as active as she had been. Vomiting began and increased, also constipation, which grew steadily worse, the bowels moving only with drugs. At 9½ months she began to hold her head backward, and for the last three was in much the same condition as when first seen. She had the breast only until her sickness began, but after that was given in addition oatmeal gruel, milk and beef-juice and during the last few days a modified milk. She slept but little, and cried almost constantly. All motion seemed to cause pain and increased and brought on spasm. The spasm was never entirely relaxed even during sleep. Fairly developed and nourished. Skin smooth and soft. Color fair; fontanelle normal size; heart, lungs and abdomen normal; no rosary; no glandular enlargement; the arms and legs were in a state of almost constant contracture, which never entirely relaxed. Any motion or excitement caused an increase of the spasm with crying. During the more intense spasms the head was much retracted and the back in the position of moderate opisthotonos. Respiratory spasm was marked, the chest being fixed in the position of full inspiration. The arms

were rigid, their position, however, varying in different attacks. The thumbs were always strongly adducted in full extension. The fingers were flexed at the metacarpo-phalangeal and first phalangeal joints and extended at the second; sometimes extended at the first phalangeal joint also. The legs were held rigidly, the thighs being crossed, the knees extended, the feet slightly extended and the toes flexed. The facial phenomenon was not elicited; Trousseau's symptom was marked; the knee-jerks were normal. The electric reactions and sensation were not examined.

As the history of the other children suggested some trouble with the breast milk, and as this child did better on a mixture of modified milk and breast-milk than on breast-milk alone, the nursing was stopped and she was given modified milk only. She was also given small doses of bromid of potassium. There was no improvement in the epasm, vomiting and constipation. There was also a progressive loss of weight and a continuous temperature, ranging from 99 to 100 degrees. She was therefore sent to the Summer Hospital at Rainsford Island on June 14 and remained there for more than a month. While there she vomited constantly and lost weight steadily. The dejections, however, were normal. Her temperature ranged from 99 to 101 degrees. The contractures continued undiminished. During the next three weeks she improved in every way. She cried less, slept all night and had spasms only when disturbed. The symptoms increased again, however, and she was lost sight of until November 22. During this time she was kept on a modified milk of very low percentages, ordered when she was last seen. She had emaciated to a skeleton, and was very weak. She was vomiting a little. The bowels were constipated but the dejections were normal in character. She slept well and relaxed entirely during sleep. She was quiet when awake but had more or less spasm most of the time. As she was then sixteen months old she was given starchy foods in addition to milk. Passive motion and light rubbing were also advised. Improvement from this time on was slow but progressive. The vomiting ceased but the bowels remained somewhat costive. Gain in weight and strength was steady. The spasm diminished slowly, remaining longest in the hands. It left them about March 1, 1898.

TREATMENT.

It is evident from the obscurity which still exists with regard to the origin and nature of tetany that there can be no specific treatment. As what evidence there is, however, all seems to show that the disease is due to toxic poisoning of some sort, treatment may be directed to the prevention of the formation of toxic substances, and to their elimination, if already formed. It is probable that many of these toxins are absorbed from the alimentary tract and some from the respiratory tract. Others may be produced as the result of abnormal metabolism. The production of alimentary toxins can be best prevented by a suitable diet. Regulation of the diet is probably, therefore, the most important method of preventive treatment. Intestinal antiseptics may also be of use, and are, at any rate, worthy of a trial. The formation and absorption of respiratory toxins can be best prevented by a liberal supply of fresh air and sunlight. Anything which tends to improve the hygienic surroundings is of use. Elimination must naturally take place largely through the intestinal tract, and to a less extent through the kidneys and skin. Emetics, purgatives and lavage of the stomach and colon tend, not only to favor elimination, but also to prevent the absorption

of toxic substances already formed. The kidneys must be kept active by a liberal supply of water and possibly by mild diuretics. The skin may be stimulated by proper hygienic measures.

Symptomatic treatment is also important and consists largely in the avoidance of excitants of spasm and in the employment of antispasmodics. Excitants to be avoided are cold, handling, noise and excitement. Antispasmodic treatment may be local, by the use of such measures as warmth, warm baths, inunctions of oil and light massage, or general, by drugs. The bromids and chloral are the most useful, but opium, belladonna, valerian and musk may be tried. During convulsions chloroform or ether may be administered by inhalation.

NEURALGIA AND NERVE CRIES.

Presented to the Section on Neurology and Medical Jurisprudence, at the Forty-ninth Annual Meeting of the American Medical Association, held at Denver, Colo., June 7-10, 1898.

BY CHAS. HOWARD LODOR, AM., M.D.

CHICAGO, ILL.

From time immemorial certain phases or symptoms of disease which have been uncertain in their pathology or whose pathology has been unknown, have been classified under general terms, vague and uncertain; and these terms have varied with the ages. Time was when the humors of the body accounted for all manifestations of disease which could not be accounted for or classified by the scalpel, inspection, or inductive reasoning from the most simple and elementary medical facts. Humors have passed, and we now classify such disturbance as manifestations of a diathesis, or of chronic rheumatism or gout, of the presence in the blood of nerve irritants, as uric acid, toxalbumins, auto-infections, etc., or as due to the cries of sensitive nerves for pabulum which an impoverished circulatory medium no longer furnishes them, and call them neuralgia.

The longer I study the matter, the more am I inclined to believe that a healthy nerve in a healthy perineurilemma does not ache, or if it does so, the case is rare. Furthermore, the term "neuralgia" should

be excluded from our vocabulary as an entity, and confined to the very few and rare instances where nerves ache for no, as yet, apparent cause. The term itself is a good one but is not so definite and limited as the word "cough," and should not be used except to define a symptom.

With such prelude, I take up the study of certain forms of pain not directly associated with a definite cause. The sources of pain are many. Under the title of my paper, I wish to include only such nerve cries as are not directly and immediately traceable to some evident physical cause. For purposes of classification, the source of such pain may lie within the nerve itself or its environment, or may be found in irritants carried to the nerve in question through the medium of the circulatory fluids or in defects in said fluids. In the first class may be grouped the following:

1, chronic inflammatory processes not recognized as neuritis; 2, old adhesions the result of inflammatory products, present after all active inflammatory process has ceased; 3, changes in the perineurilemma from chronic rheumatism and arthritis deformans; 4, pressure from cicatrices and new growths. Particularly is this true in syphilis where gummata or periosteal nodes or inflammatory changes about canals, cause pressure upon nerve trunks; 5, reflex, or rather referred pain, particularly common about the fifth nerve; 6, fatigue pains common in the back and about the loins and head; 7, hyperesthesia of certain sets of nerves, and under this head I would include neurasthenia and hysteria.

In a second class may be arranged the diathetic causes as follows: 1, the accumulation of the gouty acids in perineurilemma and sheath; 2, anemia, collemia, malaria, auto-toxins and poisons, as lead, copper and mercury, diabetes, syphilis.

A third class might be made of causes for pain following and consequent upon nerve conditions as outlined in the preceding two classes and be tabulated as follows: 1, change in blood-pressure; 2, in atmospheric pressure; 3, change in lymph-pressure and in lymph constituents.

The above classification makes no mention of the crises of ataxia, of eye strain, of the various nerve cries connected directly with the eye, ear, nose, throat, nor with any source of pain usually clearly defined and referable to definite and recognized local disease, and I make no effort in the present paper to cover the whole field which my title might include, but do desire to call attention to certain points which are either overlooked or to which little or no attention is given, and yet which play an important part in the causation of pain.

Gray defines neuralgia as a "functional disease of the sensory fibers of the peripheral nerves, and manifests itself by pain." Such definition covers the meaning of the term as ordinarily used, but a closer study of all cases of pain, not related to an organ or definitely diseased part, limits the neuralgia, *per se*, to narrower and narrower fields, and almost all cases of pain, when full investigation has been made, are better classified under other heads than that of neuralgia.

The subjects which have been prominently before me in my studies are: 1, the effect produced by inflammatory adhesions and by the products of, and exudates remaining after inflammations, modifying or restricting the functioning of nerves so hampered; 2, lymph stasis; 3, the auto nerve poisons.

Coming to the consideration of my first cause of pain, namely, nerve cries arising from the local condition of a nerve which has undergone inflammation and whose function is more or less affected and hampered, as the result, there is room for much conjecturing. Nevertheless, certain clinical facts point so evidently that their pointings must be true. It has been my observation that a patient who has once gone through an attack of neuritis is a most delicate barometer and hydrometer, and the reason is not far to find. After a nerve has passed through its history of inflammation, resolution rarely takes place perfectly. Three conditions follow in the wake: First, a development of connective tissue in the bed of the nerve, tying it down more or less; second, a development of connective tissue in neurilemma and perineurilemma, making the whole envelope of the nerve thicker and less pliable; third, and perhaps more important than all, a partial vasomotor palsy and stasis in the intimate vessels of the nerve, due to the general inelasticity. As a result, a nerve thus thickened and with poorer circulation will less readily accommodate itself to the varying swing of atmospheric pressure and moisture. Making an average, we say that with the ordinary barometric pressure of our latitude a man of 150 pounds is under a pressure of 30,000 pounds, or 15 pounds to the square inch. Now let the pressure be quickly changed, especially in the way of taking off pressure, and a healthy vasomotor center responds at once, increases its grip upon blood-vessel structure and the lung speedily unloads the excess of gas held in the fluids under a pressure of one atmosphere and now somewhat reduced. Such is not the case with the hampered nerve. Owing to its inelasticity and poor vasomotor control, the nerve is under pressure—pressure of blood and pressure of gas—and the owner of that nerve is suffering torment long before the storm has broken. Mills, in his recent work upon the nervous system and its diseases, quotes from Mitchell and Catlin, and shows a diagram clearly establishing a close relation between pain and barometric pressure and the temperature. He says at the center of the vast area of every moving storm is a moving space of the greatest barometric depression, known as the storm center, which the rain usually precedes by 550 or 600 miles and around which is a forerunning area of neuralgia.

A similar explanation to that given above will account for the neuralgia coincident in our climate with east wind and consequent upon the amount of moisture or rather, dampness, in the air and its conductivity of both animal heat and electricity.

The subject of lymph stasis and the daily fluctuations in size of the brain and body are matters of only passing moment to healthy nerve fibers; but, to nerve trunks bound down by the products of old inflammations and with imperfect vasomotor control, such swaying in the peri-vascular spaces and in the lymph-channels may be of great moment. The diurnal ebb and flow of lymph, besides the thrice daily ebb and flow, causes a daily change in size of the parts of the body, which change is physiologic. It is fairly well established as a fact that the circumference of a limb varies materially in the twenty-four hours, being smallest in the morning, at the time of lowest temperature, and largest in the late afternoon and evening, when the daily temperature swing has reached its highest point. This fact offers a ready explanation of the difficulty which rheumatic and gouty patients, whose vaso-constrictors are more feeble and

whose lymph-channels are especially prone to fill in the evening, have in wearing articles of clothing in the evening which were comfortable in the morning. The same character of reasoning will explain the evening ache of dentals when the nerve is no longer actively inflamed but is surrounded by an area if not of infiltration, of lowered resistance. The curious and intense ache present in Morton's metatarsalgia, coming on after sundown and particularly noticeable after a full meal, was somewhat difficult of explanation until the lymph-tide was recognized as a possible cause for the disturbance. It has been a common observation that the extremities swell, or rather increase physiologically, in size toward the close of the day, and the development of pain has been rightly ascribed to such increase in size, but why such increase took place remained a mystery, excepting as the increase in size of peripheral blood-vessels might account for it.

Physiologists, such as Starling and Heidenhain, are busy thrashing out the truth of lymph excretion, of lymphagogues, and lymph secretion, and the war goes on right merrily. From the facts thus far established it would seem that the endothelial cells of blood-vessels do not actively excrete lymph, but as in the case of the kidney, exert a selective action upon the plasma so that certain substances are strained or sieved through. Lymph is not of the same specific gravity as the plasma of the blood. It may contain an excess of proteids, also of tissue waste, as urates and uric acid. L. B. Mendel in the *Journal of Physiology*, Vol. xix, declares it is never of the same specific gravity as the blood, and contains a larger proportion of sodium chlorid and of sugar than is found in the blood.

Heidenhain has called attention to the existence of two classes of bodies which, when injected into the circulation have the power of largely increasing the flow of lymph. The *first class*, which includes peptones, extract of crayfish, mussels, etc., and at times, egg albumin, acts particularly by greatly increasing the exudate from the blood, making both blood and lymph over-concentrated. The *second class*, such as sugars and neutral salts, acts on the tissues, robbing them of water, making both lymph and blood more watery.

The above facts may eventually assist in solving the curious nerve and circulatory disturbances which we see after the ingestion of certain articles of food, and particularly when there are individual idiosyncrasies. It would also help to explain the phenomena of angio-neurotic edema. Owing to the readiness with which uric acid is thrown out of the general circulation and the lessened resistance of certain nerves in the gouty and lithemic, and the fact that the lymph-channels make ready bayous for gouty salts, we have added means for comprehending gout neuralgia.

The part played in the production of pain by my third division of causes for pain, namely, the various substances in the body produced by imperfect tissue metabolism or turned into the circulation by resorption from the intestinal tract, is engaging our attention more daily, as studies are being pushed deeper into the unknown domain of digestion and assimilation in the circle outside the intestinal tract. That the presence in the blood of certain substances which are inimical to healthy nerve life does cause pain is beyond question. The gouty and lithemic are particularly prone to neuralgia, so are the syphilitic and

alcoholics, and those who suffer from intestinal fermentation; all which disorders are recognized as potent in causing dyscrasia of the blood. Diabetes is an exciting cause for polyneuritis, but is also causative of nerve cries which can not be ascribed to neuritis. Von Noorden states that the earliest sensory disturbances to be found in diabetes are paresthesia, anesthesia and hyperesthesia of varying degree and location, and pain and cramps. These neuritic symptoms appear very early, and may be among the first symptoms of which complaint is made, and the painful areas are located more usually in the third branch of the trigeminal and in the crural nerves.

Haig, in his last edition of "Uric Acid in Causation of Disease," makes casual mention only of uric acid as causing neuritis. He states it as the cause of everything from gout to anemia, chlorosis to melancholia, but as a grave cause of neuritis or of nerve pain, only hints. Marshall, years ago, recognized the fact that odontalgia was not caused by dental caries alone, but that many a gouty patient would have an intense odontalgia after a heavy meat and champagne dinner without any cause to be found in the teeth per se, and that such pain did not yield to the ordinary dental measures, but to attention directed to the body condition at large. Pope justly calls a combination of alcohol, tobacco and a late supper, "a powerful trinity in the causation of neuralgia."

Whether uric acid or the biurates be the cause of gout, certain it is that the gouty are especially prone to most obstinate and severe forms of neuralgia, and that these attacks are often recurrent and paroxysmal and prone to resemble articular explosions of gout. Lyman states that no part of the body escapes their incidence, and their duration varies from the most transient fulgurant pain to the un-intermitting and persistent agony of chronic inflammation. Gout particularly affects the sciatic nerve, next the trifacial and intercostals. If the statement that "a nerve once inflamed is a point of lessened resistance afterward" be true, it is not hard to understand why gouty nerves should be prone to suffer. The lowering of external temperature causes a rise in acidity in the extremities of the body. Such acidity favors the throwing out of circulation and the precipitation of gouty acids.

In concluding I wish to call attention especially to the influence upon the general nerve structure and particularly upon the higher nerve-centers of the lymph-flow and its constituents. The readiness with which sugar and the lithemic salts pass out of the general blood-circuit into lymph-channels, and the irritating effect of such materials, has helped me to understand many nerve cries obscure in their origin. That delicately balanced condition of body economy which Haig dwells upon as collemia, in which the circulatory fluids of the body are saturated with lithemic products held in solution by the alkalinity of the blood and requiring but the slightest change in alkalinescence to deposit or throw down such salts, explains beautifully the rapidity with which sudden neuralgia may take place from apparently slight perturbing causes. It is wise in all cases of obscure nerve pain to hunt farther for its cause than is to be found in the self-satisfying term "neuralgia."

Orthoform.—In prurigo and herpes zoster orthoform has been found extremely effective by Horn. He uses it as a dry powder or in a 10 per cent. salve.—*Die Arztl. Praxis*, 13.

A FURTHER CONTRIBUTION TO THE STUDY OF THE DIFFICULTIES OF DEFECATION IN INFANTS.

Presented to the Section on Diseases of Children, at the Forty-ninth Annual Meeting of the American Medical Association, held at Denver, Colo., June 7-10, 1898.

BY THOS. CHAS. MARTIN, M.D.

LECTURER ON DISEASES OF THE RECTUM IN THE COLLEGE OF PHYSICIANS AND SURGEONS, CLEVELAND, OHIO.

At last year's meeting of this Section I offered for inspection a score of dried specimens of the infant's lower intestine as evidence that the infant strains at stool because of the imperfect development of the anatomic features concerned in the mechanism of defecation. Examination of those specimens revealed the fact that the wall of the infant rectum and sigmoid flexure is thin, compared to that of the adult. It was impossible to distinguish the longitudinal muscular bands which are so apparent in the gut of the adult. It was observed that in the fresh state the mu-

the beginning of the middle third of the rectum the mesentery rapidly shortens, but apparently completely invests the upper third of the rectum. (See Figs. 13 and 14.) The middle and lower thirds of the abdominal rectum are not so completely invested with peritoneum, and present upon their posterior parts a vertical lane bare of peritoneum, from the borders of which the peritoneum is reflected in lateral directions. This uncovered part of the gut is not applied directly to the sacrum and coccyx, and there is a space between, which is occupied by loose connective tissue. The distance from the dorsal parietes to the gut is variable here, being from one-half to one-fourth of an inch—1.27 to .63 cm. At the beginning of the middle third there is usually a gradual decrease in the length of the peritoneal band as it descends, till it is one-eighth or possibly one-sixteenth of an inch—.32 or .16 cm.—in length at the last bone of the coccyx; it rapidly shortens from this point to its termination. The parietal peritoneum descends over the ischial tuberosities and approaches nearly to the ental

FIG. 13.—Side view of specimen shown in Fig. 12. The mesentery from sacrum and coccyx to the rectum is fairly well shown, but is shown shorter than in the fresh state, alcohol immersion, varnishing and drying having shrunken it. Observe also how nearly the peritoneum approaches to the anus.

FIG. 14.—The reverse of the view shown in Fig. 13.

cous membrane constitutes a greater part of the gut-wall of the infant, and that the mucous membrane and muscular coats are more intimately adherent than in the adult. The infant gut being very deficient in muscular elements, the intrinsic power of peristalsis can not be present in that degree necessary to it as a component factor of defecation. It was shown that the relations of the peritoneum to the rectum of the infant also contribute to the difficulties of defecation, as also does the relatively great length of the descending colon and sigmoid flexures.

In the child the mesentery of the sigmoid flexure and rectum is of great length. In young children the length of the sigmoidal mesentery from its attachment to the parietes to its invagination of the lower loop of the sigmoid is often greater than the distance from the promontory of the sacrum to the distal bone of the coccyx. From the sigmoido-rectal juncture to

FIG. 23.—A semilunar valve taken from the specimen shown in Fig. 18, drawn as seen under a glass magnifying fifteen diameters. A, mucous membrane; B, fibrous tissue; C, bundles of circular muscular fibres; D, vein; E, artery; F, vein; G, artery; H, areolar and adipose tissue.

sphincter muscle. In the newly born the peritoneum is situated within one-fourth inch—.63 cm.—of the anal skin. (See Fig. 13.)

The disproportionately great length of descending colon and mesentery of the infant obviously contributes to the possibility of angulation of the gut. The angulations constitute a resistance to the descent of the feces.

The third feature obstructive to defection in infants is the rectal valve. It is a feature and factor which not only has not been recognized, but is one whose very anatomic existence has been most ingeniously and persistently disputed. In each and every instance of more than three hundred subjects examined by me these valves have been present, though in varying number and position in different subjects. In most cases there are present three valves; in some there are four, and in others there are but two. The infant specimens shown indicate that the valves are particularly well-developed at birth, spanning, as they do, one-half the diameter of the gut.

The microscopic section which was shown was taken from the middle of the lower valve of the adult specimen exhibited. (See Fig. 23.) It was shown magnified fifteen diameters. The thickened state of the mucous membrane over the free border of the valve fortifies that point against the increased friction which that part must necessarily bear. Beneath it is noticeable the heavy layer of fibrous tissue which gradually diminishes till it is lost at the valve base. Bundles of circular muscular fibers are seen in the middle of the valve. At its base are seen arteries and veins for its special nutrition. This structural arrangement makes this organ the typic anatomic valve—evidence of fibrous tissue in the organ is a distinct addition to our knowledge of this subject. It must be readily seen that the presence in the rectum of such a structure as an anatomic valve would be essentially obstructive to the passage of feces.

The bony pelvic outlet in the infant is so contracted that the limits of anal expansion are such as to almost defeat the passage through it of other than fluid feces. The average transverse diameter of the newly-born infant's pelvic outlet is but little more than one-half inch—1.27 cm.—the pubo-coccygeal measurement is even less. The average distensibility of the sigmoid flexure and rectal chambers, in which the feces when firm are formed, is four or five times that of the anal expansibility; thus it is readily perceived that, compared to the adult, the juxtaposition of the ischial tuberosities in the infant supplies a most obstinate obstructive factor in defecation.

Aside from the difficulties of defecation which the undeveloped state of the anatomy of the organs of defecation entail upon the infant, there are two more or less grave accidents which are peculiarly common to infants, namely: prolapse of the entire rectum and inguinal hernia. Prolapse, involving all the coats of the rectum, or complete prolapse as it has been called, is due to the great length of the mesentery with which the rectum of the infant is provided, and to the undeveloped state of the other pelvic organs and contiguous structures, which in a state of more complete development in the adult, contribute support to the rectum.

Inguinal hernia is more likely to be acquired by the infant than the adult, because of the relatively greater length of the mesentery in the infant, and because of the relatively smaller pelvis and protuberant, pot-bellied abdomen of the infant, which latter feature places the abdominal ring in almost as dependent a position in the infant abdominal wall, as the anus itself is placed in the abdomen of the adult.

These studies of the infant, when compared to similar studies of the adult, admit of the conclusion, I believe, that the normally formed infant's escape from these difficulties is ultimately assured by process of development, but the tribulations, the accidents referred to, and the dangers which are recognized as common to the period preceding adolescence make it incumbent upon us that we direct efforts toward their alleviation. Diet, hygroscopic suppositories and fluid injections which may render more fluid the intestinal contents will favor their descent through the convoluted gut, the valvulated rectum and the contracted anus. Massage of the abdomen over the region of the colon aids in 1, the development of the auxiliary abdominal muscles of defecation, and the intrinsic expulsive muscles of the intestinal wall; further, such manipulations 2, directly propel the gut's contents

along the tortuous course of the bowel, and 3, relatively reduce the obstructive features of the valve. If there be an overgrowth of the rectal valve, and if it form an almost impassable barrier to the descent of the feces, it may be in some measure overcome by dilatation, which may be effected through the means of the gently-introduced trained finger. In case the defective valve exists in the form of a diaphragmatic stricture or membranous septum with a central aperture, the valve may be safely cut by a method described by the writer elsewhere.¹

As at birth the pelvic bones are not yet united, and as the ramii of the ischium and pubes are still quite cartilaginous, it is obviously possible that a little energy intelligently directed from without will spread the pelvic outlet, whereas the infant labors ineffectually with his forces applied, as they are, at a disadvantage from within. The nurse, therefore, may be directed to pare away her nail-ends, lubricate her fingers and gently introduce the smallest finger through the anus. Daily gradual dilatation of the infant's pelvic outlet should be practised, graduating from finger to finger until the required degree of dilatation be reached. The introduction of the finger, independent of its dilating uses, incites the mechanism of defecation to action. Rachitic subjects with abnormal contraction of the pelvic outlet demand forcible divulsion of the ischial tuberosities.

That form of complete prolapse which is so common to infants, for the anatomic reasons already specified, is to be managed by the employment of the procedures already proposed, together with proper posture of the little subject at the time of defecation, and after the prolapsed bowel has been returned. That posture which favors the production of prolapse is the one of flexion, which is naturally assumed for defecation. Extension of the limbs is the position which best overcomes the tendency to prolapse, and therefore the subject should be required to take either the erect-extended or the horizontal-extended posture at the time of straining at stool as a preventive measure. The best position of the patient for the reduction of the prolapsed rectum is that known as the knee-chest posture, and the best posture to prevent its immediate recurrence is that of horizontal extension. As an auxiliary means of retention of the rectum the buttocks may be strapped together with an adhesive band.

Acquired inguinal hernia in infants should not be operated on, if its control be possible by means of the truss, for the reason that the natural growth of the infant and consequent expansion of the pelvis converts the mesenteric to parietal peritoneum and shortens the range of movement of the intestine, and such growth also places the abdominal ring in a more protected situation, and removes it from the excessive pressure of the intestine—thus the child outgrows hernia. These observations on hernia have no reference whatever to those forms of congenital hernia which depend upon errors of development of the inguinal canal or of its contents.

¹ See paper by the writer presented in the Surgical Section.

Injection for General Weakness.—In severe gastro-intestinal infections in infancy (F. Fede.), the following is recommended as an injection: bihydrochlorate of quinin, asafetida, tincture of musk, aa 1 gram; boiled water 120 grame; yolk of one egg. For two or three injections during the twenty-four hours.—*Semaine Méd.*, September 28.

WHAT ARE THE SYMPTOMS OF NEPHRITIS?

BY ROBERT T. EDES.

JAMAICA PLAIN (BOSTON), MASS.

This question was asked in an editorial of the *JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION* of July 23, 1898, the writer in his comments seeming to intimate that the subject has been complicated rather than simplified by some of the more modern observations, and that it is surrounded by needless mystery.

It is true that the diagnosis is not quite so simple as in the days when "albuminuria" covered almost the whole ground of renal pathology, while prognosis was brief and gloomy, and the clinical history prolix only, because of the great variety and severity of the symptoms which might precede the fatal termination. That, however, was longer ago than the "few years" claimed by the editor. Forty years ago it was known that albumin was to be found in the urine in many cases which were not to be considered Bright's disease, and the number of conditions in which it may occur has been constantly added to until at last a "physiologic albuminuria" has been spoken of.

The significance of the presence of casts has undergone similar changes in estimated importance and for similar reasons, until the writers in the *JOURNAL* (Haines and Skinner, Jan. 29, 1898) claim that by their method of careful search casts may be found in samples of urine even from persons in perfect health. When these facts are brought into connection with another set of (as I believe, exceptional) observations, in which it is shown that the progress of a well-recognized nephritis may be accompanied by neither of these important conditions—once considered almost, if not conclusively, pathognomonic—and when we find also that the person with the high arterial tension shown by the sphygmogram—which has been thought so highly characteristic that Mahomed used to speak of "Bright's disease without nephritis"—may live for years without developing any others, the bewildered student finds himself driven to the conclusion that the only persons who are free from the symptoms of Bright's disease are those who have the disease itself.

Now, whatever we may think, as a matter of taste or gratitude or scientific accuracy, of the propriety of naming diseases and symptom-groups after physicians, it seems clear that if we do so, the name should be applied to the conditions described by the writer, and not to something else more or less frequently associated with it, even if the subsequent author calls his the "true —'s disease" and all others "spurious" or "pseudo-". Certainly Dr. Bright described well-recognized organic gross disease of the kidney, associated during life with the presence in the urine of albumin, detected by heat. He did not describe the hypertrophy of the heart as the disease, although he well knew that it was a frequent accompaniment, nor the high tension of the arteries, nor the casts which he had not seen, nor the traces of albumin which the reagents had not been invented to detect.

It seems that a portion of such obscurity and confusion as still surround the matter—which the editorial in question seems to have exaggerated—is due in part to confusion in nomenclature, in part to a tendency to overestimate the importance of rare exceptions, and to go from one extreme to the other, concluding that so soon as a symptom has been shown not to be pathognomonic it has no longer any value; and in part

to another error which sometimes accompanies the development of greater accuracy in diagnosis and the recognition of earlier stages of diseases or perhaps even of a tendency thereto. I mean the mistake of attributing the clinical history and prognosis based upon the study of well-developed and advanced examples to cases which have been recognized by more refined methods at an earlier stage—so early, in fact, that it may often be doubtful whether they have gone far beyond the bounds of normal activity or structure. Such recognition is of the highest value for prophylaxis and therapeutics, but should be utilized with the utmost caution in prognosis, both for the sake of the patient's peace of mind and the physician's reputation; and this caution is never more necessary than in connection with the very class of diseases under consideration.

The following chain of reasoning—although I admit that it can not be found laid down in the books in exactly this form—does not greatly misrepresent the usual state of feeling among the profession not so many years ago, and not yet wholly extinct among the laity. A single observation of albumin in the urine meant albuminuria; albuminuria meant disease of the kidneys; disease of the kidneys meant, in the great majority of cases, chronic Bright's disease; Bright's disease meant steady progress toward a not remote fatal termination, which might be interrupted at any time by various accidents which would still more accelerate it. Some of the links of this chain are weaker than others, but all of them have, of late years, been subjected to searching examination, and they may be taken up in order.

1. As to transient, physiologic or cyclic albuminuria: Albumin in small quantity has been found either constantly or at frequent short intervals in the urine of many persons supposedly healthy or more frequently among those quite young who are not actually sick but are a little below par in general condition. When the intervals are more or less regular, usually coinciding with the periods of sleeping and waking, or more properly of lying down and getting up, it is called cyclic. In some exceptional cases a condition of constant albuminuria may last over months or years without manifest impairment of the general health.

In the majority of cases transient albuminuria is provoked by exposure of some kind, frequently such as tends to raise the arterial tension and thus bring more pressure to bear on the kidneys. Cold bathing is the typical example. Other conditions, however, figure prominently among the statistics of those who have found large proportions of albuminurics among healthy persons. Such are, for instance, excessive exercise, and vaccination, and the expectation of examination. What the local conditions are which give rise to transitory albuminuria it is difficult to say, as such cases are not likely to be the subject of postmortem examination, but it is not going far to surmise that they involve some real, if slight and transient and easily reparable, change in the epithelium of the glomeruli. But a single observation showing albumin should not be considered of great diagnostic value, unless the quantity is large or there are other symptoms confirmatory of the suspicions attaching to its presence, or unless repeated examinations show that it is more than temporary.

An exceedingly important point in regard both to this question and the next one, is that of the test used.

TABLE 1.—ALBUMINURIA AMONG PERSONS SUPPOSEDLY HEALTHY.

Author.	References.	Class of cases.	Number examined.	Albumin found.	Per cent.	Albumin in larger amounts than 0.1 per cent.	12-25 cgr. per liter.	Less than 12, trace.	Remarks.
Clarke.	Brit. Med. Jour., Aug. 16, 1887.	Persons expecting examination.	20	3	15				
Leube.	Virchow's Arch., vol. 72.	Healthy soldiers.	119	19	16	Not more than 0.1 per cent.			After exercise. Before exercise, morning urine 4 per cent. albuminous. Cylinders and blood corpuscles not found. Tested by boiling.

		Age 15 to 25.	10	5	50				Casts, 2.
		Age 25 to 35.	10	4	40				Casts, 3.
		Age 35 to 45.	10	3	30				Casts, 1.
		Age 45 to 55.	10	2	20				Casts, 2.
		Age 55 to 65.	10						

¹ Brannan remarks upon the unusually large percentage found among candidates for life insurance, and quotes Rabagliati as accounting for this condition by saying that the well-to-do have more renal disease, because they eat and drink too much. This apparently does not apply to Shepard's figures.

As more delicate reagents have been employed, the proportion of cases in which albumin—or what is claimed as such—has been found increases, until with "Tanret" (iodohydrargyrate of potassium) it is said to occur in the majority of cases of healthy persons; rising to 40 per cent. in "soldiers returning from a review," and 100 among "cuirassiers just vaccinated" and "infantry after a cold bath." (De la Celle. See table.)

It is obvious that such a test as this is worse than useless, for it can give no useful information to the physician, while if results based upon it be communicated to the patient, it will implant in his mind an apprehension which no subsequent explanations can fully remove. There is no clinical value in a test which draws no line, not even an obscure and uncertain one, between danger and safety. The same remark will apply in less degree to some others, which shade in delicacy from the "Tanret" to the ordinary heat and nitric acid tests—not the "heat with nitric acid" test, which should never be used.

Probably these last mark most clearly and conveniently the point at which the line can best be drawn between the presence of albuminuria and "no;" i. e., a negligible amount of, albumin; and the physician who adheres to these, carefully used, will make less trouble for himself and his patient than with any other. He may, however, for convenience and to make sure,

sometimes find the acid brine or picric acid useful, and it is within the bounds of possibility that his attention might be called by even more delicate ones, in some exceptional cases, to a renal trouble that might otherwise be overlooked. Any errors of omission of this kind, however, would be as nothing beside those which he would make upon the other side if he adhered to any very excessively delicate test as a criterion of well-developed renal disease. If from 75 to 100 per cent. of healthy persons are known to have albumin in the urine, there is no use in searching for it, for experience tells us that only a much smaller proportion than this are the probable subjects of future renal disease, and neither its presence nor its absence can tell us which are the ones.

Some years ago I collected from various sources a number of tables showing the frequency of the occurrence of albumin, which are reproduced here with some subsequent additions. Among the most noticeable are those of a committee of the Connecticut Medical Society, of which Dr. Shepard of Hartford was chairman, which will be seen to differ very widely from many collected from nearly the same class of persons, which they might be supposed to approximate most nearly. Dr. Shepard says explicitly that he has taken no notice of cases where the albumin was not shown by the heat test. This paper is to be found in the Proceedings of the Connecticut Medical

TABLE II.—ALBUMINURIA OF ADOLESCENTS, CYCLIC AND ACCIDENTAL ALBUMINURIA.

Author.	Reference.	Class of cases.	Number examined.	Casts found.	Remarks.
Moxon.	Guy's Hospital reports, xxiii.	Young man.		Very few.	Albumin of adolescence; later renal calculus.
Dukes ²	British Med. Jour., Nov. 12, 1881.	Young men and boys.			Some transient; some recover after years, large proportion first stage Bright's disease.
Johnson.	British Med. Jour., Dec. 6, 1873.	Young men.		None.	After bathing.
Vogel.	Virchow's Handbuch, vi.			None.	Cases observed by the year; no symptoms; may be slight organic changes.
Pavy.	Lancet, Oct. 17, 1885.	Men mostly young.		None.	Cyclic and intermittent; oxalate of lime; no bad health.
Pavy.	British Med. Jour., i, 271, 1876.	Weston (the pedestrian).		Abundance, hyaline and granular.	During walk; in 1888 in active business.
Ultzmann.	Wienermed. Presse, Jan. 23, 1870.	Physicians.	8	None.	Urine clear, dark, acid, 1025 to 1035; nothing else abnormal.
Edlefsen.	Mittl. Ver. Sch. Holst. Aertz., 1866 to 1881.		3	Not mentioned; a few times.	Albumin after exertion; supposes no renal diseases (excludes doubtful opalescence).
Fürbinger.	Zeitsch. klin. Med., 1879-80.	Officers, young physicians, blooming young people.		Small cylinders.	Officers after exertion, urine scanty, saturated, containing uric acid, gravel.
Marcacci.	L'Imparziale, May 12, 1878.	Young physician (self).		None.	Albumin absent from night urine; present in day; increased by exercise. [appeared by rest.
Rooke.	British Med. Jour., Oct. 19, 1878.	Young woman, 14 to 16.			Intermittent; none in morning; always at night; disappears.
Kinnicntt.	Arch. of Med., 1882.	Young persons.		None.	Transient; some associated with high specific gravity; uric acid, oxalate of lime; arterial tension low.
Simmons.	Sacramento Med. Jour., April, 1887.	Young physician.		None.	Cyclic; none in early morning; concentrated, four years' standing; now absent; oxalate of lime, uric acid.
Canfield.	Philadelphia Med. News, 1887.	Man, aged 32.		None.	Cyclic; none in early morning; maximum at 8 A.M. and in evening; well.
Klemperer.	Deutsch. Arch. f. klin. Med., xii, (as quoted by Canfield.)	Student.			Cyclic; maxima nearly as above.
Stokes.	Lancet, March 10, 1888.			None.	Four years; lithiasis from beer; when lithiasis abates [albumin also.
Stokes.	Lancet, March 10, 1888.	Athlete.			Albumin twenty years; now prostatic and cystic trouble.
Ralfe.	Lancet, ii, 1886.	Man.		None.	Albumin six years; urine pale, abundant; density high, much pigment.
Fergusson.	British Med. Jour., ii, 1878.	Youth of 17.		Not mentioned.	Albumin five years; puffiness of eyelids.
Rendall.	Thèse de Paris, 1883.			Very rarely.	Albuminuria from digestion (hematogenous).
Engel.	New York Med. Rec., Oct. 1882.	Several young men.		None in those which mention'd.	Occasional albuminuria after unusually heavy meal.
Engel.	New York Med. Rec., Oct. 1882.	Two young men.		Present.	Later symptoms of renal disease more marked.
Merklen.	Med. Press and Circular p. 7, 1885.	Young man, 16 (symptoms acute).		None.	Rather weakly; albumin from noon to midnight; more in night.
Fischl.	Deutsch. Arch. klin. Med., xxix, 217.	Patients mostly with gastric or hepatic colic, jaundice.	10	None.	Albumin temporary.
Fischl.	Deut. Arch. klin. Med., xxix, 217.	Metrorrhagia, collapse.	4	Few.	Albumin temporary.
Bull.	Nordiskt Archiv.	Physician, aged 27.			Continued at least two years.
Kinnier.	N. Y. Med. Rec., June 19, 1886.	Young men.	3	None.	Albumin during middle of day.
Coupland.	Lancet, July 10, 1886.	Girl of 16.		None.	No albumin in morning; later, irregularly present; no crystals of uric acid or oxalate.
Fox.	Lancet, Dec. 12, 1891.	Man, aged 31.		On second examination.	Albumin constant; re-examined after two years; casts found; health apparently excellent.
Fox.	Lancet, Dec. 12, 1891.	Man, aged 60.			Albumin occasionally for 17 years; casts sometimes.
Tiemann.	New York Med. Jour.	Males under 21.	186		Albumin in fifty-one cases, 27.5 per cent.
Brannan.	New York Med. Jour.	Man.			Albumin without renal disease; used to eat three raw eggs in morning; eggs stopped; albumin disappeared.
Edes.	See text.	Young woman.		A few, mostly hyaline.	Albumin first found thirty-one years ago after puerperal convulsions; from time to time ever since a trace of albumin and casts.

²In a later article (Lancet, 1891, Vol. ii, pp. 1327-1382), Dukes remarks that these cases are much influenced by posture. Albuminuria occurs after standing. Also, these persons liable to faint on standing.

Society, N. S., Vol. iv, p. 203, Hartford, 1888, concealed under the highly descriptive title, "Matters of Professional Interest." This covers many thousand cases.

2. The more or less persistent presence of albumin is always of importance enough to call for a minute and careful search for other symptoms, but if these are not found in such a way as to decide the question, there has been a good deal of difference of opinion as to how seriously this one standing alone should be taken. This point is especially to be emphasized in reference to life insurance, that is as to the remoter prognosis.

Most authorities who have had the opportunity to study the subject from that point of view are quite clear that albuminuria constitutes a decided objection to a risk, although their own statistics, as well as the general experience, proves that there are many albuminurics, by the ordinary tests—that is, tests about as delicate as heat—who are in no immediate danger of chronic nephritis of sufficient intensity to give rise to any other symptoms for many years. In the face of the facts that in the vast majority of cases and under normal circumstances, no albumin whatever detectable by heat escapes by the urine, and that when it does so, some slight departure from normality may usually be found, and that when persistent there is in nearly all cases a deterioration of the general health (Munn, Dukes, Brannan), it is safe to say

that albuminuria always means some trouble with the kidneys. Whether in all cases it has a right to the dignity of nephritis, is largely a matter of nomenclature.

We are originally furnished with perhaps twice as much renal tissue as is sufficient to take care of the excreta which normally pass in this direction. There is no disturbance of the balance of health until the secreting power is reduced, either by loss of substance or loss of function, or unless on some special occasion the demands upon it are considerably increased. Thus it is perfectly possible that there may be some portion of the structure sufficiently damaged to let through a small portion of albumin without affecting the rest of the kidney, just as there may be, for instance, a few specially irritable regions in the nasal passages or in the colon which secrete more than their normal amount of mucus without impairing the functions of the remainder.

The observations of Munn (Medical Investigation in Life Insurance) showed that among the albuminuric candidates for life insurance the percentage of mortality was considerably above the normal, and that they all exhibited, after a lapse of time, a falling off in complexion and general appearance. Clement Dukes (*Brit. Med. Jour.*, Nov. 12, 1881, and *Lancet*, Dec. 12, 1891), who has for years given attention to the albuminuria of adolescence, is far from regarding it with indifference and has on at least one occasion

³ Refers to many authors who speak of the absence of albumin.

TABLE IV.—OPINIONS.

Author.	Reference.	Remarks.
Gull.	Guy's Hospital Reports, xxii (reported by Moxon).	Albuminuria as common as spermatorrhea.
Johnson.	Brit. Med. Jour., Dec. 13, 1879.	Latent albuminuria means serious trouble.
Teissier.	Lyon Méd., 1887.	Subjects of cyclic albuminuria; probably all destined to goutiness.
De Havilland Hall.	Lancet, Feb. 18, 1888.	Albuminurics should not be assured.
Pye-Smith.	Guy's Hospital Reports, Vol. xix.	No person who has albuminous urine (by usual tests) can be considered eligible for life insurance.
Brannan.	New York Medical Journal, July 4, 1891.	Derangement of function will sooner or later end in structural change in kidney.

TABLE V.

	Accidental.	Neurotic.	Irritative.	Asystolic.	Chronic parenchymatous nephritis.	Chronic interstitial nephritis.	Subacute nephritis.	Cerebral disease.
Daily quantity of urine.	Normal.	Increased.	Diminished.	Diminished.	Diminished.	Increased.	Diminished.	Increased.
Specific gravity.	Normal.	Diminished.	Increased.	Increased.	Normal or increased.	Diminished.	Increased or little change.	Diminished.
Albumin.	Varies in different cases; only occasionally present, perhaps.	Small amount.	Small amount.	Varies.	Much.	Mod'rate, none sometimes.	Moderate.	Small amount.
Casts.	None or a very few hyaline.	None or a very few hyaline.	Few.	Few or many; hyaline and granular.	Many of all kinds.	Hyaline, epithelial, granular.	Hyaline, epithelial, granular.	Very few.
Other sediment.	Not important.	Not important.	Uric acid, oxal. lime, ep. stained with bile pigment blood?	Uric acid, oxal. lime, ep. stained with bile pigment blood?	Uric acid, oxal. lime, ep. stained with bile pigment blood?	Uric acid? or not important.	Epithelium, urinary salts.	Not important.
Arterial tension.	Normal.	High.	Normal or high.	Diminished.	Diminished.	Increased.	Not much changed.	High.
Dropsy.	None.	None.	None.	Lower limbs.	General.	Face, feet and shins.	Slight.	None or very slight.
Eye ground.	Normal.	Normal.	Normal.	Normal or hemorrhages.	Album. retinitis, but less common than in next.	Albuminuric retinitis, hemorrhages.	Sometimes lesions, which disappear.	Optic neuritis.

recognized in a college student, applying to him for more advanced renal disease, one of his former albuminuric boys. He says: "The cases of early albuminuria, so common in the young, constitute the early stage of what may eventually become developed into that chronic disorganization of the kidneys termed Bright's disease."

One of the most striking illustrations of the fact, that while albuminuria may be an exceedingly chronic symptom, it is not to be considered as without significance may be found in the history given by Dickenson of an old family in which this symptom has been known to exist for at least four generations, while the family portraits seemed to him to give strong grounds for the suspicion that it extended back to a time when it was not sought for in the urine, but revealed itself by the complexion and general appearance to the experienced eye of later physicians. Most of the persons affected died at a comparatively early age, and in one case the kidney examined and reported in connection with Dickenson's paper was clearly in a con-

dition of chronic nephritis. (Trans. Path. Soc. London, 1888-89, xi, 144.)

3. The distinction between acute nephritis and the forms of chronic renal degeneration more distinctively known as Bright's disease without any prefix, is too obvious not to have been at once recognized. The relationship between them was also well understood, so that although it was known that the acute might give rise to the chronic form it was by no means necessarily so, any more than it was usual for pneumonia, for instance, to cause consumption, although such a thing might, under specially unfavorable circumstances, occur. But there seem to be cases between the two where the duration is distinctly too long and the intensity of the symptoms too slight to be considered acute, and on the other hand, do not deserve the inevitably fatal prognosis supposed to be connected with the diagnosis of Bright's. When a case of this kind recovers—either absolutely or relatively—it may be claimed on the one hand by the therapeutic optimist as a "cure of Bright's disease,"

or may be, on the other, belittled by the skeptic as only "an acute case which was rather slow in getting well."

4. The knowledge of the extreme chronicity, as well as the insidious origin, of well-marked Bright's disease could only be acquired by the lapse of time, and many instances of so-called mistakes are due to this fact rather than to any error in diagnosis, properly speaking. A very interesting case is reported by Francis Hawkins (Trans. Clinical Society of London, 1892-3, xxvi, 216), of a medical man who had consulted Dr. Bright himself, and had been told by him that he had renal disease, and that death was inevitable within two or three years. He gave up his London practice, but died forty-three years later of cerebral hemorrhage. Stories of this character are apt to be told of many distinguished physicians, who see in their consulting practice a large proportion of cases that are difficult and obscure. They naturally contribute greatly to the comfort and hilarity of the laity. In the present one Dr. Bright may have been perfectly correct in his diagnosis and failed so signally in his prognosis, because he was necessarily unaware of possibilities now familiar to all. The time that has elapsed since the practice of searching for urinary symptoms in cases—other than those where it is absolutely forced upon us—has become a common one, has taught us many things that he could not have known. Such cases show what we are finding out more and more in regard to many diseases, that an experience based on the hospital and deadhouse, which represent almost entirely the last stages of chronic diseases, is not trustworthy as the sole guide in general practice.

A young woman had post-puerperal convulsions in September, 1867. Soon after and for a year later albumin was found in the urine. She was confined again in 1870 and in 1871, the children being sickly. Subsequent examinations of which I have notes are as follows, and I have a strong impression that there were others of the same character:

November, 1874. Albumin and casts, medium-sized, granular and one or two small hyaline. April, 1878. Considerable albumin; small hyaline casts. September, 1887. Large trace of albumin; one cast. September, 1898. S. G., 1016; perceptible opalescence on boiling; slight cloudiness with picric acid; no perceptible line on underlying with nitric acid; several small hyaline casts. In 1887 she called to see me, and again in 1898, and is in fair health.

It certainly appears more probable in a case of this kind that some small local lesion has remained the same without extension to surrounding tissues, than that any general deterioration either of blood, of arteries, or of renal structures has withstood the shocks of subsequent pregnancies and the wear of thirty years without impairment of the general health.

On the other side of the albumin question, i.e., with reference to those cases of decided nephritis which have been for many years known to exist, where albumin is temporarily or even for long periods absent from the urine, they only emphasize the importance of inquiring in regard to *all* the symptoms in *every* case. Equal or superior in importance to albuminuria, comes the presence of casts, and then the quantity of urine and its solid constituents, condition of the heart and arteries, edema, nausea and anemia.

Several elaborate articles, based on a careful study, not only of the more obvious symptoms, but of the

chemic constituents of the urine for twenty-four hours, have recently appeared by Stewart (*Am. Jour. Med. Sci.*, December, 1893; *Med. News*, April 14, 1894) and Edwards (*Amer. Jour. Med. Sci.*, October, 1898). The first named of these authors seeks to establish a special form of nephritis on the basis of absence of albuminuria. It seems very much like the "renal inadequacy" of Sir Andrew Clarke. In all of his (Stewart's) cases casts were found, but he seems to lay special stress in his diagnosis on the deficiency of both water and solid constituents in the twenty-four hours' urine. Of this it may be remarked that he has set his normal standard very high (35 gm. of urea) and, what is of perhaps more importance, there is little reason to suppose that such soluble and highly diuretic substances as urea and chlorid of sodium fail to appear in the urine in sufficient quantity on account of any structural difficulty in passing them through.

A comparison of cases of renal atrophy from hydro-nephrosis or renal calculus shows how small a remnant of secreting structure is sufficient to filter through large quantities of water, presumably carrying with it such salts as are very easily soluble therein. This condition of things points much more strongly to a deficient metabolism, which is a pathologic condition, but has no necessary relation to the kidneys in particular, except from the fact that its products happen to come through those organs. It may indicate to the shrewd observer one of the directions in which danger may be anticipated, but it is not nephritis.

If, in such a case as is reported by Edwards, nephritis is suspected when there are "no suggestive cardio-vascular findings, no albumin, no casts, no decrease in total solids, specific gravity or quantity," no edema mentioned, and this possible diagnosis is confirmed by the autopsy, we can only congratulate the physicians on their acuteness and feel that when a diseased organ presents absolutely no symptoms of abnormality in its products, and no evidence—except so very indefinite a one as nausea—of impaired function, nobody but a clairvoyant can be blamed for overlooking it. The "prealbuminuric stage of Bright's disease" of Mahomed and some others should be described rather as "a condition of the system, and in particular of the arteries, of which nephritis is one among several possible results."

The significance of a very small number of casts can not be quite so distinctly defined as that of a quantity of albumin determined by some standard test, because so much depends upon the skill, the luck, and especially the patience of the observer. If the painstaking method of Haines and Skinner (*l. c.*) is followed, we can be reasonably sure that no casts have escaped us. It is possible that after this method has been in use for some time we may find that they are as common as excessively small quantities of albumin, in which case the symptom must cease to have any great value, unless the chief weight is laid upon their character rather than upon their mere presence. If, however, we adopt a less rigid and more convenient standard, that is, the examination with a low power of several drops of sediment from urine that has stood for a number of hours without decomposing, or obtained from the centrifugation of a considerable quantity, we stand on about the same level of accuracy with the heat test for albumin. Most statistics are not very trustworthy as to determining the importance of the finding of casts under these conditions, as there is no guarantee for even the degree of thor-

oughness just described, but there is no doubt that casts are often found in small numbers when they do not greatly add to the gravity of the evidence afforded by small quantities of albumin. So that now opinion is changing in regard to them, somewhat as it has already done in regard to albumin, and there is danger of their significance being overlooked or underestimated.

Two important limitations should be made. The casts, or so-called casts, of irregular outline and longitudinal striation, often tapering off into a tail at one end, and named, probably correctly, "mucous," are of no consequence whatever, or, at the most, if numerous, are significant only of a certain amount of superficial irritation of the kidneys. They may, however, occasionally deceive an inexperienced observer. True casts may be divided into two chief classes: the small and medium hyaline, which are probably formed in the caliber of tubes which retain their epithelium; and the larger sized ones which contain, or are chiefly composed of, epithelium more or less degenerated; and also more homogeneous ones which are apparently formed in tubes from which the epithelium has been shed. The second class can often be found at the autopsy *in situ* in kidney undergoing various forms of degeneration. They signify parenchymatous nephritis and by their number and character, give important information as to the extent and progress of the lesion. They are naturally of much more serious import than the small hyaline ones carrying now and then a cell. The large casts formed by solid masses of degenerated cells molded in a tube previously denuded of its epithelium or of which the lining forms the outer layer of the cast itself, and those solid ones with a sharp outline, frequently bearing the marks of a more or less complete resinous fracture, are of the most unfavorable significance, but are not often met with until the question of diagnosis has long ceased to be the most interesting one.

Shattuck (*Boston Med. and Surg. Jour.*, 1894, cxxx, 613) has had many examinations made for the purpose of determining the frequency of casts, especially in persons of advancing years, and finds them more common as the patients are older, and not to be closely connected with other symptoms of renal disease, nor of special unfavorable import in such persons. This observation, however, is far from proving them of no significance, but shows simply the fact that there is always a reserve of renal structure and that if its destruction goes on slowly it may be years before that reserve is exhausted. The renal atrophy may be merely keeping pace with a diminishing call for activity of function dependent upon a less active metamorphosis of tissue. It corresponds to the post-mortem observation of a narrow zone of atrophy just underneath the capsule, dependent upon a chronic interstitial nephritis, which has not destroyed any large proportion of secreting structure.

Mitchell (*New York Medical Times*, xxiii, No. 7, p. 201, July, 1895) has examined his records of persons whose condition was known for seven years after albumin and casts have been found. He concludes: "Where casts are found, together with albumin"—he used heat test—"the mortality is nearly three times as great (30 per cent.) as in the non-albuminous cases (11 per cent.), and more than twice as great as in those who have albumin without casts (14 per cent.)."

A part of the difference between the non-albuminuric and the simply albuminuric cases was thought

by Mitchell to be attributable to "accidental albuminuria," but in the presence of a microscopic examination that can hardly be of much importance.

It is only in the early stages and in regard to the preliminary questions that the albumin and casts are to be considered separately. In the permanent presence of albumin it is not safe, so far as most observations go, to assume the absence of casts because they are not mentioned, and on the other hand it is certainly not usual to find casts without the presence of a trace of albumin.

It is safe to say that the presence of albumin by the ordinary tests is proof of some disorder in the glomeruli, either as to blood pressure or soundness of epithelium or both, and that casts, according to their structure, either exudative or degenerative, prove disorder of the epithelium lining of the tubes, whether merely irritative or amounting to total disorganization. How extensive or how slowly progressive these changes may be is another step in the diagnosis, but they are never strictly physiologic, except in the sense that normal and natural reactions to abnormal conditions may be called so.

A condition which very frequently accompanies one form of nephritis—so frequently, indeed, that it has placed its stamp thereon and almost withdrawn it from the category of simple local inflammations, making of it a constitutional disease—is the high arterial tension. So early is it that Mahomed used to speak, not only of a "prealbuminuric stage of Bright's disease," but of "Bright's disease without nephritis." But this also fails of pathognomonic significance in the absence of the two symptoms just under discussion.

The sphygmograms of many cases of neurasthenia closely resemble those considered as characteristic or intestinal nephritis, that is, of an arterial pressure continuing high through too long a part of the diastolic interval, and indicating too great resistance to the passage of the blood in the distal portion of the circulation. The absolute pressure in the neurasthenic cases is probably less in the average than in the true arteriosclerotics, but the opposition to the escape of the blood through the arterioles is such in proportion to the force with which it is thrown into them, that a tracing is produced, similar in form, though often lacking in amplitude. This condition, as I have observed in many cases, is in no way a precursor of chronic nephritis. (*Boston Med. and Surg. Journal*, May 19, 1881 and July 18, 1895.)

Many years ago I took some tracings from members of a medical club, among which were two which would, I think, by any one who had given attention to the subject, have been considered highly characteristic of chronic interstitial nephritis. One of these confrères died three years afterward, not of interstitial nephritis, but of interstitial hepatitis. The other, after practicing for many years longer, gave up finally on account of sciatica and the infirmities of age, and died at 85, never having given any signs of nephritis.

On the other hand, although the usual conception of the nephritis and the high arterial tension as two, perhaps equally important, parts of a common morbid condition, is applicable to the great majority of cases, yet it is probable that in some the arterial and cardiac lesions are distinctly the result of a nephritis of purely local origin.

I recall the case of a boy with atrophy of the kidneys, evidently dependent upon obstruction in the

urinary passages, as shown by dilatation of the ureters and trabeculation of the bladder, who had a heart pronounced by competent authority to be hypertrophied, a condition for which there was nothing to account except increased arterial tension, which had not, however, been observed during life. There had been peculiarities of micturition, although after death there was no obstruction to the passage of an instrument through the ureters or urethra in either direction.

It is my belief that the origin of many cases of interstitial nephritis in young persons, where no other sufficient cause is to be found, might be successfully sought for in some difficulty of micturition, often functional, dependent upon irregular and incoordinated muscular and nervous action. (See *Bechterew. Neurologisches Centralblatt*, Sept. 15, 1898.) This may have been so slight as to escape serious notice but yet sufficient to set up a back pressure in the ureters and kidneys which would lead to hydronephrosis and atrophy. (*Medical News*, Aug. 10, 1899.)

The fact, now well known, that a man who has albumin in his urine is not thereby doomed to an early death, and the later statistics of Shattuck and Mitchell confirmed by many isolated observations, showing a similar significance as attached to casts, are likely to lead to false conclusions if they are taken to prove that these positive and distinct conditions are without important meaning. A marked change in either direction in the daily quantity of urine, as determined by actual measurement, is of great value as a symptom, but an excess or especially a diminution in comparison with the average usually stated as normal, should not be too hastily referred to renal derangement. In fact, in the early and doubtful stages, to which this paper chiefly refers, the kidneys are fully able to take care of all the water, urea, and probably all the other soluble salts, brought to them in the blood.

Pollakiuria or frequency of micturition, especially at night, although it should call for a careful examination of the urine, may be entirely unconnected with any disease of the kidneys or even of the bladder, being often of purely neurotic origin.

The amount of urine is influenced by many circumstances beside the condition of the kidneys: the vascular tension, which, as we have seen, is not necessarily connected with nephritis, the activity of the skin and bowels, probably the dryness of the surrounding atmosphere, and in particular the habits of the patient as regards the quantity and diuretic quality of liquids taken. A considerable diminution in the daily amount of urea excreted does not signify that the kidneys are inadequate to cope with it, but that for some other reason the metamorphosis of nitrogenous tissue is diminished. A copious flow of pale urine of a specific gravity below the normal average will for months or years carry off all the urea formed.

How far this applies to other substances less abundant, less diuretic, and less well known; perhaps to some others formed only under pathologic conditions, is not so certain. The presence of autogenetic poisons as the cause of many symptoms in renal disease is one of the interesting questions yet to be answered by the physiologic chemist and clinician together. There are grounds for suspecting the uric acid group and some coloring matters, but the proof against them is not conclusive. The ordinary urates are not so bad as they look.

PRECORDIAL AREA IN CHILDREN.

Presented to the Section on Diseases of Children, at the Forty ninth Annual Meeting of the American Medical Association, held at Denver, Colo., June 7-10, 1898.

BY H. B. WHITNEY, M.D.

DENVER, COLO.

At the Pan-American Congress in 1893, I presented a paper on "The Normal Precordia in Infancy and Childhood," and this paper was afterward published in the *Archives of Pediatrics*. Subsequent observation has not changed the views expressed at that time, nor have I anything to add to them. I shall, therefore, merely give you the briefest possible résumé of the original paper, my present purpose being to mark out the precordia in a few children of different ages, and invite criticism of the results obtained.

I have ventured to bring up this subject again because, in the first place, I regard the question of the normal precordial area as of the greatest practical interest and importance; and if my observations have been correct, it seems to me desirable that the facts should be universally accepted. In the percussion of the heart we are dealing with a measurably constant and unvarying quantity; our results ought to be proportionately reliable. I am aware of the great differences of opinion which have always prevailed in regard to the precordial area, and these have been so divergent as to produce in some the conviction that anything like unanimity of opinion is hopeless; that differences of method and skill will always make percussion of the heart a purely individual matter. I can not take this pessimistic view. To me there is nothing in physical diagnosis more definite and more certainly ascertainable than the normal area of precordial dulness. I am, therefore, hopeful that a practical comparison and discussion of methods may at least further an agreement among those who are here present.

Hitherto no text-book in pediatrics has done more than state in a general way that the precordia of infancy and childhood is enlarged. Weil emphasized the fact in 1879, but made no distinction as to age. Other writers since Weil have simply repeated his statements. I will give, in illustration, only a short paragraph from that latest and most admirable book on pediatrics, "Holt's Diseases of Infancy and Childhood:" "The outline of the area of relative cardiac dulness, *especially in small children* [*italics mine*], is proportionately larger than in adults. . . . According to Sahli, the limits are as follows," and then limits are given, corresponding precisely to those originally found by Weil, and to those which I shall attempt to demonstrate at certain ages. This persistent reappearance in the text-books of the old and, according to my conviction, incorrect statements, is the second reason why I again call your attention to my former paper.

The gist of my own observations may in a word be stated as follows: 1. Up to the age of 5 years the precordial area is not perceptibly enlarged, but corresponds practically with that of the adult. This statement concerns mainly its right border, which in the adult is a perpendicular line corresponding very nearly with the *left* border of the sternum. 2. From the age of 8 years up to and considerably beyond the age of puberty, the normal precordia differs markedly from that which is found in earlier life. Its right border now extends a half inch or even more beyond the *right* sternal margin; while the upper border is

in the second interspace, and toward the *left* the precordia extends one-fourth to one-half of an inch beyond the mammillary line. 3. During the fifth, sixth and seventh years, conditions are inconstant. The enlarged precordia of childhood may be found even in the fifth year, but is decidedly the exception. In the sixth year it is much more frequent, in the seventh it occurs in the majority of cases, while in the eighth year, as before stated, it becomes a constant and, in my experience, unvarying find.

As to method of percussion: It is presumed that the stroke is light, or at most moderate in force. My results have been always obtained with the fingers alone; I have never used a pleximeter. In percussion of the right heart, I have always laid special emphasis upon the note obtained over the upper and lower halves of the sternum as compared with each other. If the sternum is everywhere equally resonant, I fail to see how any enlargement of the heart toward the right can be affirmed, except in cases where there is some abnormal condition of the upper mediastinum. If, on the other hand, the lower half of the sternum is duller than the upper half, such dullness can be attributed only to the precordia; a view which may always be confirmed by more careful delineation of this dull area toward the right.

With these brief preliminary remarks, I beg leave to show you several presumably healthy children of different ages, in whom I have marked out the precordial area.

DISCUSSION.

Dr. J. N. HALL, Denver—"The doctor has asked us to point out any errors which we see in his method of percussion. I am glad that I have little to say in the way of picking to pieces his results. I think, however, the matter demonstrates several things outside of percussing the chest. It shows us there is room for us to learn something about even a matter thought to be so well understood as percussion. I do feel, however, the Doctor makes one point rather too strong, that is, that the question of cardiac area can be established. That is a matter perhaps, upon which the greatest variation exists among physicians, and concerning which our opinions must vary as long as our methods and ears vary. By the man who does his percussion with the whole arm, using the hand as a hammer, such an area will not be marked out. But now many more are using the finger in percussing than formerly. Three times in my experience I have seen chests absolutely full of fluid. In one case a diagnosis of advanced phthisis with impending death was made some years ago, and the man is now working on the railroad. In those cases the physician did not percuss properly. We may judge of what is beneath by the feeling of the finger as well as by the sound. Illustrating this matter further, I will say that some two or three years ago a physician applied to me to ask whether I considered his cardiac area enlarged. I told him I thought it was somewhat enlarged. Another physician examined him and said he believed it was normal. Six gentlemen, some of them of prominence, examined his heart; three said that it was normal and three that it was slightly enlarged. As long as our opinions will vary in that way we can scarcely say that the matter of percussion is one of absolute accuracy. As long as we have the lung causing different shades of sounds, we will certainly have some room for discussion as to the absolute area of dullness in any heart.

Dr. JOHN H. MUSSER, Philadelphia—"There is no department of physical diagnosis that is more difficult than that which attempts to determine the size of the heart by percussion. It is one that I have been working at constantly for a long time and I am not yet satisfied as to my ability to positively state the size of the heart. In fact, I do not believe any one can

state the size of the heart. We can state the relative and absolute areas of dullness. However, to me, the matter has been of such extreme difficulty that I am always glad to learn from others their methods. If I understood Dr. Whitney right, in early life the right border of the cardiac dullness extends to the left edge of the sternum.

Dr. WHITNEY—Approximately.

Dr. MUSSER—Then it extends to the right border later on?

Dr. WHITNEY—It increases with the age of the child.

Dr. MUSSER—I am satisfied that in children the area of cardiac dullness is farther out than we have been taught in the text-books. Even half an inch beyond the right edge of the sternum may be considered normal. The varying size of the heart and the changes in respiration are the factors which make it so difficult to indicate by percussion the size. I refer to the varying size of the heart with systole and diastole. Hence one must percuss constantly and under various circumstances, and not with one method but with various methods, if possible, as control investigations, and even then one can not but fail often to satisfy himself as to the size of the heart. I have felt this difficulty so much with the ordinary methods of percussion, in which I rely more upon the pitch than anything else, that I employ also the method of tapping the chest with the finger and rely upon the vibrations. I also use auscultation. But I have found good results from palpatory percussion. I compare that which I get from the various methods with the child in the upright as well as in the recumbent position and also in full inspiration and full expiration. Then I feel that I can come to some conclusion as to the size of the heart. But the very fact that we have to go through so many measures, and the very fact that the heart is so variable from its action and respiratory movements, leads us to believe that our present methods are unsatisfactory. I am quite sure that palpatory percussion is familiar to you all; yet, probably it will not be amies to say that it is simply using the finger, with which you can feel resistance. In fact, in this case, I would say the line, if anything, is a little above where Dr. Whitney has indicated. We percuss down the mammary line until we get to the liver dullness, and then by percussing we find a line about the fifth rib that turns off to the sixth rib and marks the cardiac dullness. All these various methods of examination should be used, and even then you will come back in half an hour and find that you are an eighth or a quarter of an inch out. I am very glad to have heard Dr. Whitney's method. It is the only way we can expect to get anything—by hammering away. I am satisfied the question will be settled with precision before very long.

Dr. BABCOCK—I do not feel at all qualified to make comment, but would desire only to raise two or three points or queries which have suggested themselves to me: 1. Can the latitude at which the Doctor makes his observation exert any influence upon this matter? 2. Can the history of the child make a difference? We know that pericarditis in children is a much more frequent disease than is recognized, and pericardial adhesions may exist which are never recognized. The question has suggested itself to me whether in any of these children, for instance, there can be a history of some previous disease in the course of which a pericarditis leading to subsequent adhesions might have been present and yet not recognized. We know that when an adherent pericardium exists it may not give rise to any signs, and yet it does materially influence our findings as to the size of the right heart. 3. The query arises as to whether it makes any difference, in the percussion of a child's heart, whether it is done soon after a meal or when the stomach is empty. The heart is a very movable organ and I would like merely to inquire if it is possible that the stomach of a child soon after a meal might, by a pressing upward of the diaphragm, raise the apex of the heart sufficiently to cause the heart to assume more of a horizontal position, and whether

this might not deceive one in his observation on the precordial dulness of the child? In the cases presented here this morning, those from 8 years upward certainly presented a very different note along the sternum, and the Doctor certainly has demonstrated his claim. Whether in the younger ones there is a slight though sufficient difference to determine that the precordial area is larger than the Doctor supposed is a matter perhaps of individual difference.

Dr. A. C. COTTON, Chicago—It seems to me that perhaps the most instructive part of the clinic today is the point that I would like to make in regard to auscultation, namely: the importance of the personal equation in all of these cases. Here we have acknowledged experts, yet I venture to say that if each one were asked to make a diagram of the area of cardiac dulness, we might have as great a variety of diagrams as we have of examiners. Dr. Whitney, himself, in demonstrating the area of dulness, observed that the blue line in one case did not correspond with the area of dulness. Dr. Musser tells us that he sometimes finds the area of dulness has moved a fraction of an inch in a comparatively short time. Every one who has attempted percussion knows that much depends on the pressure of the finger. Condensation of tissue under pressure will easily give a note that is readily demonstrable. A very nice experiment is to have each one in a clinic examine the area of dulness, and cut a pattern, and then compare the patterns. It is very astonishing the different patterns you will get, and not only from novices either. That there is much difference in this respect I think everybody will admit. When Professor Babcock tells us that he finds an enlarged area of dulness, I take it that means to him, and that there might not be an enlargement of the area of dulness to Dr. Whitney or somebody else. So it seems to me this personal equation will always stand between the different examiners.

Dr. ROSA ENGLEMAN, Chicago—Perhaps it would be better if more of our observers gave us observations as to physiologic and anatomic peculiarities in children as compared with the adult. That is a study in which too little is done. It occurred to me also that the individual factor as related to the children might play a part in this matter of percussion; or, as Dr. Babcock has also intimated, perhaps disease. I noticed in one case the chest showed the child was decidedly rachitic, and that might interfere with the normal growth and development of the heart. Enlargement in the area might be due to the development at this age, especially between 7 years and puberty. The difference, is not so appreciable between the ages of 1 and 7 years as between perhaps 7 and 12 or 13. I think these are factors that have to be taken into account in this anatomic and physiologic study of the heart of children.

Dr. HERBERT B. WHITNEY, Denver—In regard to Dr. Fischer's question, my idea was to bring up the question of percussion, which alone is used in determining the size of the heart. It is a question, when there is an increased area, whether we could judge that the heart was enlarged. The precordial area obtained by percussion has very little to do with the size of the heart. I thank Dr. Babcock very much for his suggestion in regard to the distention of the stomach. I think that may have much to do with the fact that I found over the lower part of the sternum at the fifth year a note, which is, it seems to me, as good if not better than over the upper part. The remark about rachitic cases, by Dr. Engleman, is a good one. I have rejected some rachitic cases because the dulness always extends beyond the sternum. In closing, I want to say one word in regard to the question of resonance in the fifth interspace in cases of pericardial infusion. I have been associated with Dr. Rotch in this work, filling the heart with water and percussing it. I have found that I can not feel that the Doctor is correct in that. I have examined a great many cases of pericardial effusion and enlargement of the heart, and I have come to the conclusion that, as far as my experience goes, in

those enormous hearts that extend far over to the right, in which there is some difficulty in distinguishing it from a pericardial effusion, we find dulness everywhere: sometimes absolute flatness extending over to the right of the sternum. How one can make a differentiation between pericardial effusion and enlargement of the heart in that way is beyond me. I have not been able to do so.

A STUDY OF THE HEART AND CIRCULATION IN FEEBLE-MINDED CHILDREN.

[PRELIMINARY REPORT]

Presented to the Section on Diseases of Children, at the Forty-ninth Annual Meeting of the American Medical Association, held at Denver, Colo., June 7-10, 1898.

BY J. MADISON TAYLOR, M.D.

AND

F. SAVARY PEARCE, M.D.

PHILADELPHIA.

In the Transactions of the American Academy of Medicine (Vol. ii, pp. 164 to 189) for 1895 the writers considered the "Causes of Mental Impairment in Children," and the "Causes of Imbecility and Idiocy," the "Varieties of Idiocy," and "Pathology of Idiocy," respectively.

Since that time a study more particularly of further somatic changes in the mentally feeble children has been continued, and we have carefully gone over the records of the 532 cases reported in the above communication, with the object in view of tabulating systematically the results obtained as to the "Heart and Circulation in Feeble-Minded Children." In feeble-minded children a large proportion are of defective development in other organs.

A large amount of new material accumulating through our own further studies, and in reports kindly made by physicians in charge of institutions for feeble-minded children, both public and private, have added much to the statistical value of our records, which will be recorded *in toto* and presented in the near future.

It is here intended to make an elementary report to preface the elaboration which will be followed by a fuller compilation.

Heart in feeble-minded children.—Arhythmia is a notable feature in about half the cases, and especially so in proportion to the aberrant forms, as the Mongolian type of idiot. Intermittent heart we noted but seldom, and indeed in our experience it is more associated with functional disturbances than with organic (brain) changes, as though inhibition overflow mechanism was always at work in varying degrees in the mentally feeble. Thus some sort of pulmogastroic stimulus always persists: whereas in functional brain or heart disturbances nature seems to be able to afford complete silencing of the myocardium, again to proceed undisturbed. This also seems to be the case with the ill innervated papillary muscles, for transient, shifting, precordial murmurs not transmitted can, we think, not be explained on any other physical basis, and true organic murmurs are not common. Cases illustrating this phenomena will be detailed in the future work.

Tachycardia occurs in 50 per cent. of imbeciles, depending much on the degree of brain capacity and type of case—more marked in idiot savants and in microcephalic idiots.

Brachycardia is not an unusual phenomena, and occurs more in hydrocephalic, slight cerebral pressure cases, and in the sporadic cretin, in which latter the use of thyroid has increased the pulse-rate perma-

nently, along with the bettered mental and physical condition of the child.

Increased area of precordial pulsation exists in about one-third of the cases of imbecility, in one-half of which the hypertrophy is not sufficient to account for, and, we take it, must be due to transmission of unharmonious muscle-action, as implied in the above paragraph.

Transient thrills occur in many cases and more at the apex, perhaps—but this is to be further studied—due to close proximity of the apex at the sixth rib to the chest wall.

Transposition of the heart we have not met with, nor of other organs, although considerable shifting without added acute disease. Reason for the same was noted in a marked number and reminded us much of an adult case of a contortionist athlete with sequent bovine heart, in which the subject was able to shift the apex back and forth by extrinsic muscle effort. At autopsy we found a large, fatty heart and pericardial adhesions that might be causative in the shifting by the mechanism above detailed. This case was seen by one of us as interne in the Presbyterian Hospital of Philadelphia, and has been reported by Dr. R. G. Curtin, in whose clinic it occurred.

Bruits in the neck are few and inconstant. The hybrid between functional and organic murmur, as noted above by irregular valve leaflet action, was the principal lesion noted among the patients so far studied.

Pulse seems to follow less closely the result of the cardiac action, as above detailed, less frequently than is known to exist in persons of normal mentality, ruling out any gross cardio-vascular malady. It is not uncommon to detect rapid heart with synchronous pulse—but only temporarily—and the next fifteen minutes perhaps both fast or both slow, or indeed, vice versa.

There is also apt to be much difference between the two radial or two dorsalis pedis pulses—all in fact out of true co-ordination, as may be suspected on thought by the disturbed, ill-made governor—the brain mass of stunted, deficient micro-chemically weakened central neurons.

Conditions of edema are singularly rare, notwithstanding the disturbed and apparently markedly separately acting vasomotor systems, conditions (and of the blood) which demand wider study, as do skeletal conditions in imbeciles.

DISCUSSION ON GASTRIC DISEASES.

Delivered in the Section on Diseases of Children, at the Forty-ninth Annual Meeting of the American Medical Association, held at Denver, Colo., June 7-10, 1898.

Dr. CHARLES V. SPIVAK, Denver—It seems to me there is a certain hastiness on the part of the physician, when he comes to a child and finds it suffering from any gastric disturbance, to at once feel himself obliged to feed the baby and to devise some means how the baby should be fed. When a child is vomiting ten or fifteen times a day, the milk or any other food it is given, I think it is absurd for the physician to prescribe any food at all. I refer now to an extreme case of frequent vomiting or diarrhea, in order to take this simply as my point of departure and then we will take a slighter case. In such cases it is absolutely absurd to give the child food. All these artificial foods, prepared from cream and water in all the different ways, are simply due to the hastiness with which the physician advises the parents to feed the baby. When a baby vomits frequently or has a diarrhea, it should not have any food, but its stomach and intestines should have a rest. The

parents should be told that a day or two, or even three, of fasting for the baby will do it good and the introduction of food will do it harm. If the baby's stomach and intestines are brought into a better condition by simply fasting, or what I would rather call rest of the stomach and intestines, which is recognized as a therapeutic agent in other diseases; if rest is carried out with other devices for keeping the child at rest, and its stomach and intestines are brought into good condition, I think the food the child has had will do well if it is introduced at first in very small quantities. The first principle is not to overburden the system. So many foods are being analyzed and all that, but it seems to me that is all superfluous if we do not give rest to our little babies. If a baby has proper rest after it has assumed its former condition and can perform its natural functions, and the food is introduced in small quantities, I think this whole question of artificial feeding may be considered entirely superfluous.

Dr. WILSON of Pennsylvania—I want to endorse what the gentleman from Colorado has just said, and to go a little further and say that the most important question that usually confronts the physician in the stomachic and intestinal diseases of children is not what he shall feed them, but how he shall keep them off food. I think that is the most difficult question the physician has to consider. An article written by Dr. McFarland, which was copied in the foreign journals, on the use of hot water, impressed me very much. It is difficult to feed children who have been breast fed hot water with a teaspoon. It has been my custom to take an ordinary bottle, make it absolutely clean, put in some hot water, add some salt and put a nipple on the bottle. I do not take the salt out of the salt-cellar. I have a tablet, which is composed of chlorid of sodium and colored red. It is very attractive. I tell the mother to dissolve this in so much water. It has proven a most satisfactory method, keeping the child on this until the craving of the child for food shows it is in condition to receive food. I have had children whom I have had to wean off the hot water to get them to go back to the milk.

Dr. H. M. McCLANAHAN, Omaha—We should resort to artificial food where it is necessary. If we commence the care of the mother sufficiently early, there should, as a rule, be no reason why the mother should not nurse the infant, except in cases of disease. In one case, that of a German woman whose child suffered from colic and indigestion most persistently and constantly about twenty-three out of the twenty-four hours, an analysis of the mother's milk revealed about 4 per cent. of cream and 4 per cent. albuminoids. There, in my judgment, was the trouble. After giving the mother a thorough course of the salines, removing the albuminoids, and putting her on proper food, in about a week there was no trouble nursing the child. In the second place, as to the artificial feeding of babies, I can endorse what the gentlemen have said, but we ought to get so we can artificially feed these babies without producing indigestion. We should teach the mothers to feed them so they would not have these attacks. By changing the formula, I think it is an easy and simple thing to get a food that will meet the requirements of a case. I always give the proportions in ounces so the people can understand it. By changing the proportions there should be no trouble. This we can do without resorting to any of the patent foods. I think we should just as well give an adult patent medicine as give the babies patent foods. There are none of them similar to human milk. First, we should get a food that the child will take and digest without suffering. Next, we must get a food that will properly nourish the child. Condensed-milk babies, many of them, get along very comfortably; they get fat, flabby, and always rickety. I have never seen that fail where they were fed on condensed milk exclusively. So it is a question of getting a food that is digestible and that will properly nourish the child—a food that will not only make it fat, but will

develop its muscular and nervous system as well. We should make a food as nearly as possible identical with the normal human milk when we can not get that. That, I believe, can be done without resorting to patent foods. These societies should condemn the use of patent foods.

Dr. R. B. GILBERT, Louisville—The question of feeding the baby when the mother's milk has failed, is certainly one of the most perplexing, especially to a city population, where the cow's milk has to be obtained second hand to a large measure. I concur freely with the gentleman who has spoken with reference to overfeeding. The nursing-bottles are ordinarily made to hold half a pint for an infant a year old, whose stomach, when considerably distended, will hold only an ounce and a half or two ounces. Consequently overfeeding is one of the causes of much trouble, even if the milk be wholesome. Another matter it is well to look after is artificial feeding when the mother's milk fails. Cow's milk or possibly the goat's milk may be good, and the mare's milk has been used largely in some countries, Russia especially, but the cow is a domestic animal in this country from which we get our milk-supply, and her milk may be modified by the addition of a little water and a slight amount of alkaline matter—because it is always acid, at least shortly after it is drawn—and then secure a specific gravity of about 1032. There is much trouble getting the milk in the city and also often in the country. The milk is likely to become infected. Next to the cow's milk my experience is that condensed milk is the most reliable artificial food; it is certainly the most convenient. It can be obtained in small quantities and quickly prepared. The water should always be sterilized, which can be done readily by boiling. The assertion that rickets always follows the use of condensed milk is not true according to my experience. You can prevent that by giving the lime salts either with it or by a separate prescription.

Dr. WILSON—That is begging the question; a child fed on condensed milk alone for six months will develop rickets.

Dr. GILBERT—In that I agree with the Doctor. If you will feed a baby on any one food, except mother's milk, for six months continuously you are apt to have one or another or perhaps several derangements. One derangement you are likely to have is scorbutus, which is, I believe, likely to occur where you use condensed milk. I have seen it in two cases where the child was fed on Horlick's food. In one case it went on until there was a separation of the epiphysis of one of the bones. We were abstaining from all acid foods from the idea that acid produced scorbutus, but there we went just to the opposite extreme and gave scraped apples and fruit juices and all that and the baby got along all right. We should change the food of the infant frequently, putting him on cow's milk two or three months, then on condensed milk two or three months, and I would not object even to Horlick's food. A little chlorid of sodium should be added to the baby's food. Where I live we have an abundance of blue-grass and blue-grass milk, but the people in the city do not get good milk, because it is modified by adding water and using agents to prevent fermentation, boric acid being used frequently. If you can get good milk and add a little chlorid of sodium, the baby will get along very well. The starvation of a baby that has been overfed has, I think, been carried a little bit farther than the necessities of the case require. If you give the baby hot water six or eight hours and then resume its dietary, it will do all right. I have taken infants in apparent collapse from choleraic disturbance of the bowels and held them off on hot water six or eight hours and then given milk or condensed milk in teaspoonful doses an hour apart. I believe prolonged fasting is objectionable, because the child will reach a point after a while where he will refuse to take anything.

Dr. CHESBRO—The matter of withholding food from the infant is important, but I believe it can be carried to excess.

We not only are in danger of losing the confidence of the mothers but we may weaken the infant. After six or eight hours I believe the albumin of egg stirred up in water can be given with good results. That helps to satisfy the thirst of the child, which is intense, and is well borne by the stomach and it helps to keep up the nutrition of the child. I believe a good many of these attacks of indigestion are due to overfeeding in the first place. Indeed, I think the reason so many mothers, nurses and doctors have trouble with cow's milk and are so anxious to use patent foods is because they do not use it properly. They do not properly dilute it. If they simply dilute the milk properly and add sugar and lime water, the child will do very well. In regard to the use of condensed milk, my own idea is that condensed milk modified so simply as one of the gentlemen who preceded me said, is one of the poorest foods we have. Condensed milk, in order to approximate anything like the composition of human breast milk, can be diluted only about 1:6, but not one child in thirty can take it diluted 1:6. Other ingredients must be added, notably fat. But it is surprising to see how once in a while a child will get along on condensed milk. A child I saw, with a temperature of 103 degrees, consolidation of the left apex, some evidence of bronchitis and a loud systolic murmur, indicating congenital heart disease, I found was fed on condensed milk diluted 1:30 and in addition was having two slices of bread a day. The child had previously been doing well. As the gentlemen said, I do not believe it is possible for a child to be fed on any one food alone for any length of time without the development of rickets. For the first months of life condensed milk makes very good food. It makes fat babies, but as a matter of fact they have little resistance. Almost every child will develop rickets unless in a few months it has a pronounced modification of its diet.

Dr. S. E. WOODY, Louisville—The number of prepared and patent foods shows that they are inefficient. Cow's milk properly prepared certainly gives us something we can feed nearly every child. The use of the different formulae for preparing it and the addition of sugar of milk, is better than to use such a thing as condensed milk, particularly the Eagle brand, which contains about 50 per cent. of cane sugar to preserve it. Cane sugar is a sugar which is not digestible by the child. I have discarded the use of prepared foods almost altogether. Of course there is no rule which we can lay down by which we can feed all children alike. We have to use beef juice and different preparations of meat in order to get them over some of the disorders of digestion.

Dr. WHITNEY—I think it would be interesting if the Chairman would give us the results of the collective investigation on scurvy.

THE CHAIRMAN—There is a committee of the American Pediatric Society which has been studying the etiology and symptomatology of scurvy. We recently had the report presented at the meeting in Cincinnati. We had collected altogether 379 cases of infantile scurvy. We know that it is a distinct dietetic disease, and represents faults in diet. There are many other disturbances which are produced by faults in diet, but in scurvy it is very interesting to study the relation of the food used to the disease. The committee has been careful not to use any names. They do not say such and such a food produced the disease. We do not want to involve ourselves in any lawsuits, and we only say what food was used when the scurvy developed, and what food was used when the case recovered. Two hundred and eighteen cases had been fed on proprietary foods. Of that number condensed milk had quite a large proportion of cases. We have stated just how many cases were using Mellin's food, just how many were using malted milk, and so on through the list. The report will be published soon.

Question: I would like to ask the Chair whether the long continuance of the one food was considered, because in the scurvy of the adult occurring on shipboard the disease is not

attributed so much to the article of food as to the continued use of one article of food.

THE CHAIRMAN—It was the prolonged use of an improper food. It was not always one food, for sometimes the child had run the gauntlet of the proprietary foods.

MILK-MIXTURES AS FOOD FOR INFANTS.

Presented to the Section on Diseases of Children at the Forty-ninth Annual Meeting of the American Medical Association, held at Denver, Colo., June 7-10, 1898.

BY EDWIN ROSENTHAL, M.D.

SECRETARY OF THE SECTION ON DISEASES OF CHILDREN, AMERICAN MEDICAL ASSOCIATION—PHYSICIAN TO THE HOME FOR HEBREW ORPHANS, ETC. PHILADELPHIA, PA.

The ideal nourishment for a child is mother's milk. Nature and nature's laws have wisely ordained that the child, whose digestion is unsuitable to the foods of matured years, should be provided with nourishment which in the nature of things is most simple and bears with it the vital ingredients necessary to the child's growth. When, by certain causes, the natural method of feeding the infant is interfered with, artificial means are at hand to become the substitute for the mother and bring to the child such food as is alike acceptable to its taste and digestion, and which will add to its growth, prevent disease, and assure it a healthy childhood.

As the feeding by the mother or the "wet nurse" is called the "natural" method, so is the other, by reason of its application, entitled the "artificial" method of nourishing, and the sucklings so reared are termed "bottle babies." If we accept as facts the commendations of the various manufacturers of food preparations, nothing could be simpler and easier than to raise a new-born infant artificially. You obtain a food which purports to represent the elements of human milk, and prepare and use it according to directions. These various preparations may be more or less useful as temporary food for older children, but for new-born babes and infants in their first months, according to the unanimous view of all physicians, these foods are not suitable as temporary, much less as sole, nourishment. The only true substitute for mother's milk is to be found in the milk of animals. For this the cow is principally depended upon, and the percentage of the three important ingredients in human milk and cow's milk is shown as follows:

	Fat.	Casein.	Sugar.
Mother's Milk	3.1	1.7	6.2
Cow's Milk	2.5	3.6	4.8

This proves conclusively that cow's milk differs from human milk in the amounts of albumin (casein) and of sugar.

Sugar in milk is not intended simply for sweetening; it also has nourishing qualities, and in the artificial preparation of milk it is essential that it be used in the same proportions; and by reason of its digestibility, milk sugar should be used instead of cane sugar. The greatest difficulty met with in using cow's milk is the proportion of casein—double that of the human milk. It is, therefore, a fixed rule in practice to mix the milk so that the proportions of casein and of sugar be so apportioned that the resemblance to the human milk will be certain, not only in theory, but also in results. For the better understanding of the method of mixing, definite percentages have been presented and certain rules have been adopted which, if adhered to, will be most certain of results, and will

place the method of feeding by this artificial way upon a classic, scientific basis, with the ultimate result of making the method a truly reliable one, receiving the approval of all. I may say that this method of mixing milk is but in its infancy, and that it has not received the attention which it deserves, but I firmly believe it will, by its own worth, be brought to the notice of all, and become the only real and true way of nourishing the infant.

Many names have been bestowed upon food that takes as its basis cow's milk. The one most widely known, which had its birth in our country, and received its title from one of our members, is the so-called "Modified Cow's Milk." Unfortunately, the use of the name as well as the milk is objectionable from an ethical standpoint, being a patented article. This, however, can not change its value, nor its utility, and as methods have been devised for the preparation of such foods at home, it can be used and will continue to be used, the patent notwithstanding.

Different methods have been devised to so mix the milk as to make it as nearly like human milk as possible. Biedert's method of "modified milk" is a mixture of cream, milk and water in varying proportions, according to the age of the child. In our country Rotch was the first to place "modified milk" upon a truly scientific foundation. He has presented to the profession two methods of preparing the milk; one may be termed "the milk laboratory method," and the other the "home method." Certain percentages have been taken as a basis. The elements entering into the food were termed by him, fat, sugar and protein, and the milk laboratories can furnish "modified milk" of any desired proportions upon prescriptions of physicians, exactly as drugs are dispensed by an apothecary. While the expense of feeding an infant by this means is very great, other factors of vital importance are against it. We are, as it were, dependent upon a laboratory for the child's food, and if some accident should happen to prevent the making of the food for one, two or three days, we would be in an unfortunate predicament. The "home modification" would, therefore, appear best, and for this purpose certain instruments, with a certain fair amount of technique, are essential. Rotch, as well as Holt, gives many formulæ, suitable to children of various ages, which can be applied in various ways, and which are perfectly satisfactory. Lately I have been using "Fat Milk"—the "modified milk" food as prepared after the method of Dr. Gustav Gaertner, and known commercially as "Gaertner's Mother Milk." This food is prepared in the same manner as by Professor Rotch's method. The centrifuge is used to separate the fat, by so arranging the tube which expels the cream from the centrifuge separator that just one-half of the milk contained therein is expelled and collected. In this way, as the casein, sugar and minerals are not affected by the process of centrifuging, the percentage of the latter is not changed, while that of the fat is doubled. The advantage of this food over the other modified food is that it comes to us already prepared, and simply needs to be heated, and the cans well shaken so that the mixture be thoroughly made before using. If the food be permitted to become cooled, it will separate again, and lose the appearance of pure milk. I have used "Fat Milk" in various diseased conditions, and have had very fair success.

In the preparation of milk foods at the home, I think several points should not be lost sight of: 1, the

milk should be of undoubted character; 2, it should be free of any drugs, as boracic or salicylic acid; 3, the addition of salt to the food, and when sugar is indicated, the use of sugar-of-milk (milk-sugar) instead of cane sugar; 4, the agents used to modify milk.

The first three points can be discarded, as, all things being equal, the best milk will be the one taken, and this will of necessity be entirely free from any adulteration. The fourth point can not be so easily discarded, for upon this depends to a certain extent the well-being of the child. Rotch's formula—which may be altered to suit any case—is: Fat, 4 per cent.; sugar, 7 per cent.; proteids, 1 per cent.

Taking this as a basis to show how such a formula as this can be prepared, Rotch gives the milk laboratory formula in position, and I think no better way of explaining the method of its preparation can be given than to present both formulæ, as Rotch gives it under the name of "Modifying Clerk's Prescription."

PHYSICIAN'S PRESCRIPTION.		CLERK'S FORMULA.	
	Per cent.		Oz. Dr.
Fat	4	Modifying cream . . .	7 7
Milk sugar	7	Modifying milk . . .	4 7
Proteids	1.5	Sugar solution . . .	8 3
Mineral matter . .		Lime water	1 5
Lime water		Water	8 6
		Total	31 4
Number of feedings			7
Amount at each feeding			oz 4½
Heated at		degrees F. 167	
Time in sterilizer		minutes 20	
Remarks:			

This will be correct as long as it is obtained from the milk laboratory, but when it is to be made at home, it will be found rather a difficult subject. For this reason other methods have been used to modify milk in the home, and perhaps the one most used and most favorably known is the "flour-ball" modification. This is made by the addition of a tablespoonful of flour, previously prepared by boiling it for five hours, to a quart of milk mixture. This milk mixture is graded according to age, as within 1 to 3 months, the milk and water are one pint each; after this period the water is reduced one half-ounce every month, the milk being added to keep up to the quantity of two pints. Sugar need not be added to this mixture, or very little. Salt, however, I have always used, and in quantity hardly to be tasted. To give a taste, as well as to sweeten the food, cinnamon bark has been added. This, however, may simply be fanciful, but it is useful, especially in those cases which we term colicky babies. Among the proprietary preparations "Imperial Granum" comes the nearest to the flour-ball mixture, and I frequently prescribe it when such a food is indicated. Used as I have thus directed, it becomes one of the easiest home modifiers. Another food that is used in Philadelphia to quite a large extent is what is known as "Mellin's Food." This is also among the simplest of home modifiers. The method of its use is: milk, water and the food in varying proportions. Analyses of the different mixtures have shown it of equal value to other home methods. We can also make food of low or high proteids, fats, etc.

As the food for the infant depends largely upon the peculiar idiosyncrasy of each child, no fixed rules can be laid down nor followed. It must, however, be the rule in practice to adapt the food to the child's needs, and not the child to the food. The quantity and quality of the food is an insufficient guide. Even while it may be of the best, it may not be the one

adapted for that individual case. We should watch the stools to see if the food be thoroughly digested. If the child suffers from diarrhea, caused by the food, it would be irrational to continue its use. It is, therefore, safe to take as the guide the stools, and if we find digestion complete, the continuation of the food is in order, but if we find that digestion is incomplete—noted by the color, consistency and presence of cheesy masses in the stools—then the rule will be to at once change the food, and to remove that element that gives rise to the difficulty. Milk is the only really honest food to give the infant. Modified to fit its condition, we are on the safe path to perfect health.

DISCUSSION.

Dr. SLAGLE of Minneapolis—The great trouble with us in the West here is the milk-supply. The milk that we are feeding our children in Minneapolis is secured once a day, and the milk they get this morning is not milked this morning but at least part of it was milked yesterday. It will not be long before even in cities of this size they will have milk laboratories. We all admit that cow's milk is the best food, next to mother's milk, and can be modified to do away with the commercial foods, but at the present time we are compelled to use the commercial foods to a large extent in Minneapolis and they do, I believe, throughout the West.

Dr. R. B. GILBERT, Louisville—I was glad to hear that in modifying milk the essayist mentioned the flour ball. He has shown us the necessity of phosphorized elements in the infant's food and shown the minute work of nature in converting the material into food. But that is not new by any means, although the scientific elucidation of it is somewhat recent. In my earliest experience in baby feeding in the country it was the custom of the country women to feed a baby with what they called scorched flour, simply converting the starch into a kind of diastase or malt and retaining the phosphoric element. That was sometimes very happily used in correcting trouble in bottle fed infants. I have frequently recommended the same sort of a plan. I want to make one more point about condensed milk. The condensed milk must be fresh. If a can of condensed milk remains on the shelves of the drugstore or grocery three or four months before it is used, I do not know the changes that take place, but it is not as easily digested. I have in my town a grocer who is raising a pair of his own children, twins, largely on condensed milk. I give in addition to the milk a piece of bread. I have the grocer to bring on a case of fresh condensed milk every week and where I have bottle-fed babies in different parts of the city I send them to that one grocer, because I know then they get the milk fresh from the manufacturer.

Dr. H. M. McCLANAHAN, Omaha—I have entirely abandoned patent food for infants. I have had eighteen children under my care and they have all been well developed. I have resorted to a formula which any ordinary mother can carry out. In the first place, I have them procure the milk from as good a source as possible. When they can, I have them procure it twice a day; when they can not, I have them procure the milk and skim off the cream. Then I have the mother to take three ounces of the cream, two ounces of good milk, one ounce of milk sugar and ten ounces of water. First dissolve the milk in water, sterilized, and then add the milk and cream. This is placed in nursing bottles with cotton stoppers. A sterilizer can be made out of a bucket with a perforated false bottom. Five of the nursing bottles are placed on the false bottom in the bucket and placed on the stove. I direct the mother to leave it until the steam escapes twenty minutes. These are then placed in a bucket of cold water. When she is ready to feed the baby I tell her to place the bottle in a can of hot water as hot as the hand can stand, which is about 115

degrees, and then the temperature of the milk is about 100. Then the cotton is removed and a clean nipple placed on the bottle and the child fed. Another thing I have found by actual investigation is that that is no more expensive than any other method of feeding, not excepting condensed milk itself. Milk sugar in Omaha they can buy at 25 cents a pound. Then with a sterilized bucket, which costs very little, and a graduate which costs 10 cents, we can take good care of these children. From one of the babies I withdrew milk entirely and gave only cream and water. In one case I had to reduce the cream until there was only one-eighth cream and seven-eighths water. Then after a few days I increased the amount of cream until I got to about the normal proportions.

Dr. McCONNEL—Sometimes we have to exclude all proteids. That is based on the condition of stools. When you have a putrid diarrhea, when you are feeding milk-mixtures, you must exclude the proteids. If you continue any form of milk, you will not nourish the child. Then you must confine it to the farinaceous foods. If this is carefully watched and you stop the cow's milk for a few days if you have putrid diarrhea and confine the child to farinaceous foods and a limited diet, after the bowels become clean you can come back to the ordinary food.

Dr. JOSEPH CLEMENTS, Kansas City—Along this line I want to call attention to a boy I have today in Kansas City, over 2 years of age, ruddy and robust and fat and plump and perfectly healthy, whom I have brought up on various kinds of foods, finally coming down to modified milk. I first saw the boy when he was three months old. The mother was a trained midwife and I supposed she had a proper modification of the milk. The child was a perfect skeleton, but I put him on a modified milk and the baby got along well for a number of months. Perhaps five months afterward I found the baby in the same condition I found him at first. He was a perfect skeleton. Then I put him on Mellin's food and he again became fat and apparently healthy. The parents were Germans and came back later and told me the baby was bad again. Then I changed to condensed milk with the same result as before, that the baby improved and got fat and after a few months became ill again. They had sent for their priest, supposing the child would die, and he said there was no use sending for the doctor as the child was too far gone. I put him on modified cow's milk and he did well and has stayed in a good condition since. He was thirteen months old before the first tooth appeared. He now has a good supply of teeth and is in a good condition.

Dr. J. P. CROZER GRIFFITH, Philadelphia—I have purposely kept in Philadelphia the only out-patient department I still have, the Children's Hospital in May, June and July, because I want to be thrown with the class of people who can not get the usual modified cow's milk. I do not believe the occasion arises, or only very rarely it arises, where we can not perfectly well feed a child modified cow's milk. The difficulty is not great. We as physicians should abandon the habit of saying we will give this child an ounce of milk and an ounce of cream and so much water. We ought to think in percentages, as Dr. Rotch has so long told us, and then we think much more accurately. We do not need milk laboratories. They are useful but not absolutely necessary. It costs only about \$6 for a Babcock centrifuge and you can then test the percentage of cream your little patients are going to take. You can assume that the percentage of proteid will be 4 per cent.; it usually runs about 3.5 per cent., so the error is on the right side. I would like to refer you to an interesting paper in the *New York Medical Journal*, March 12 of this year, in which it shows how to make the proper percentages and how much milk and cream the mother is to use. In Rotch's book you will find a series of tables telling how much milk and cream you are to take. They are all right when you are in your office, but at the bedside you can not remember them. So I

have a table copied in my book. I know this is simple, for I used it on the poor people, where I have no more opportunity to get good milk than you have in any part of the country.

Dr. EDWIN ROSENTHAL, Philadelphia, in closing—Mr. Chairman: The idea I had in presenting this paper is that we can modify our foods at home. My idea is that this should be the food for healthy children, and in knowing how to properly feed your children you prevent them getting sick. If the child has putrid diarrhea, you must not continue the milk, but put it on barley water or whatever you think proper for it. Inasmuch as I have seen some accidents occur from the use of condensed milk I am not so heartily in favor of its use. The milk had some hydrosulphuric acid in it and spoiled. Whereas, in the modification I have suggested, I do not count it up in percentages, I try to make the formula as simple as possible. A point I wish to lay particular stress upon is dentition. I think the gastric disturbances during dentition are due more to the dentition than to the foods. I have a poor class of patients that I do not care to give up, and among them I have seen some remarkable results with Mellin's food and with malted milk, but I can not conscientiously give any recommendation to any food. If you modify the milk, whether in percentages or in ounces, you are on the right road to feed your child properly.

A NEW BREAD FOR DIABETICS.

Presented to the Section of Materia Medica, Pharmacy and Therapeutics at the Forty-ninth Annual Meeting of the American Medical Association, held at Denver, Colo., June 7-10, 1898.

BY N. S. DAVIS, JR., A.M., M.D.

PROFESSOR OF PRINCIPLES AND PRACTICE OF MEDICINE, NORTHWESTERN UNIVERSITY MEDICAL SCHOOL, ETC.
CHICAGO, ILL.

I do not propose to present a formal paper to this Section, but to exhibit a flour and samples of bread which have been invented and prepared by a patient of mine, who, himself a diabetic, has for a number of years experienced the need of a substitute for wheat bread.

When treatment is first begun a diabetic should be placed upon a strictly non-saccharine and non-amylaceous diet, in order to determine how far the disease can be controlled by diet. This change should not be made abruptly, but gradually, during a week or ten days' time. If the change is made abruptly, appetite often fails and malaise increases; in some cases untoward symptoms may arise and coma has not infrequently been observed to develop.

A rigid diet can not be long maintained. Nor is it necessary so to do. In the least severe cases a modicum of carbohydrates can be assimilated. Just what this quantity is can only be ascertained by a careful study of each case. Frequently, during exacerbations of the malady, a relaxation of dietetic restrictions proves better than an increase of them. Whenever a strictly diabetic regimen must be adhered to, and whenever one only slightly modified from this must be employed, a substitute for wheat bread is craved. No one article of food is more universally missed, if it must be omitted, than bread. A variety of flours have been invented as substitutes for wheat flour. Gluten flour is more universally used than any other. It is almost impossible to make palatable bread from pure gluten. All the gluten flours upon the market contain starch in considerable percentage. It is better to permit diabetics to eat a given amount of wheat bread instead of unlimited amounts of gluten bread, which contains on the average half as much starch as ordinary bread and is less palatable. Bran cakes, soya biscuits or bread, almond cakes, cocoanut cake

and peanut bread are other substitutes for wheat bread.

Bran flour contains a considerable percentage of starch. The cellulose which it contains makes it indigestible and liable to provoke diarrhea. Soya flour makes bread which is not very palatable. Analyses of the flour vary much, stating that it contains from 3 to 45 per cent. of starch. The most trustworthy analyses accredit it with about 20 per cent. of amylaceous matter. Almond flour contains from 4 to 5 per cent. of sugar, but no starch. It is so rich in oil that it also often produces dyspepsia. Cocoanut flour contains a small quantity of sugar. From it a variety of bread-like or cake-like preparations can be made. Peanut flour contains about 14 per cent. of carbohydrates. It does not make as palatable preparations as either the almond or cocoanut flours.

The flour which I show you is made from one of the many edible pine nuts. It is fine, slightly yellow, and bland in taste. The flour contains no starch and only 7 per cent. of cane sugar. If bread or other articles of food made from it are raised with yeast, this sugar is decomposed so that only a fraction of 1 per cent. can be found in the product. I have prescribed it for a dozen or more diabetics during the last few months. With few exceptions the bread and cake made from it is relished and found to be an agreeable substitute for wheat bread. Two patients at first relished it, ate it with avidity, but at the end of a week or ten days found that it caused indigestion. I urge patients to use it moderately, not *ad libitum*. Certain patients are told to use it at two of the daily meals and are permitted to use a moderate amount of wheat bread at the third meal.

This bread does not produce gases when it ferments. If it does not agree with the patient it produces loss of appetite and disinclination for it. It contains 19.82 per cent. of oil; sweet almonds contain 53 per cent., and cocoanut 70 per cent. It is therefore less likely to produce indigestion than flour products derived from either of the other nuts. It contains 55.65 per cent. of albuminoids; 6.42 per cent. mineral matter, and approximately 4 per cent. of fiber.

It is essential to the treatment of diabetes that nitrogenous waste should be lessened. This can be accomplished in part by prescribing oils and fats instead of starches and sugars. All these substances retard nitrogenous metabolism. The oil in these nut flours is therefore not objectionable, but desirable if a patient's digestion is fairly good.

I believe the best results are obtained, if substitutes for wheat bread must be prescribed for diabetics, when patients are gradually accustomed to their employment and when they are used intermittently rather than constantly. From this flour, which is known as the Chicago Sanitary Flour, a variety of food products can be made—bread, muffins, pancakes, cake, cookies, etc. Some of these must be made with baking powder instead of yeast, and contain a small per cent. of cane sugar. They are not as well adapted as the others are for diabetics, but are useful for those dyspeptics who do not tolerate amylaceous food.

Chronic Buzzing in the Ears.—For this quinin is warmly recommended by Bouchard. It exaggerates at first, but later diminishes very much the noises, not only in dry and sclerous otitis but in Menière's disease. He adds that complete integrity of the ear is rare among the insane, and that the treatment of the ear troubles is an important feature of the cure.—*Rev. de Laryng.*, October 1.

DENTITION.

Presented to the Section on Diseases of Children at the Forty-ninth Annual Meeting of the American Medical Association, held at Denver, Colo., June, 7-10, 1898.

BY JOSEPH CLEMENTS, M.D.

KANSAS CITY, MO.

Speaking of dentition in the concrete, the importance of the subject looms up considerably when we remember that there are fifty-three dental colleges in the United States, with more than fifteen hundred graduates, interested and employed in the science and art of the care and treatment of the teeth; or in more modern terms, doctors, whose practice is limited to oral surgery. And such proportions is this assuming that ere long we shall have to add to the three learned professions—theology, medicine and law—a fourth; namely, dentistry, and the instructors in our medical colleges will have to enlarge the curriculum more fully, embracing this important branch of medical knowledge, or there will be other Edward Brannigans, D.D.S., besides the one who addressed you last year at Philadelphia, whose words will be somewhat of a reproach on our lack of this necessary knowledge.

I wish here to call your attention to an excellent paper by Dr. J. W. White published in the *American System of Dentistry*, which throws considerable light on what I may term vexed problems in dentition.

I desire to acknowledge courtesies accorded me by D. McMillan, M. D., D.D.S., president of the Western Dental College of my own city, for besides the dissection of subjects in embryo obtained in my own private practice, I was permitted to examine the many skulls and casts, etc., of fetuses and children in the laboratory and museum of the college.

As a general statement I may say that the evolution and development of the teeth are the same and in the same physiologic way as that of the nails and the hair, only the nails and hair are in a more perfect state at birth. These are fully formed and developed at the end of intrauterine life. Indeed in a fetus of not more than the seventh or eighth week, the nails, I have found to be in appearance as perfect, almost, as my own, though I found no budding teeth.

Physiology and anatomy teach that in the seventh week of germ life a groove appears in the jaw, termed by Goodsir, "the primitive dental groove." From this groove and at its base papillæ arise; sacs form enclosing these, which become vascular; basic and other salts accumulate and thus the milk teeth are developed. Small grooves behind these first evolving teeth, and still during fetal life, are observable and in process of time these are converted into cavities, with their vessels and blood-supply, and thus the process is duplicated and repeated in the formation of the second or permanent teeth. Prolongations or extensions backward of and from the original groove, one at a time, and after the growth of the twenty teeth taking the place of the deciduous teeth, constitute nature's provision for the completion of the set. The nucleus of the first teeth is "the primitive dental groove." The same for the permanent teeth is "the secondary dental groove," or rather grooves, these providing for twenty of them. The remainder developing from an extension laterally from the outermost mature tooth, which, when sufficiently advanced continues or extends the groove for the next tooth, the process being again repeated, making three on each jaw, each of which may be said to be singly and

independently developed. During this second dentition the roots of the first teeth are absorbed, as I have often observed when extracting the milk teeth. The crown, neck and fang which make up the tooth are composed of the pulp, the dentine and enamel, and these are different in their histology, the various ingredients of the enamel and dentine being worked up, so to speak, by a process of calcification. As soon as this calcification is sufficiently advanced the irruption of the tooth takes place, and this occurs, beginning with the fifth or sixth month, and continuing on at intervals to the end of the second year.

The evolution of the teeth is without doubt a continuous process, the irruption of the same is at stated periods, in more or less regular order. I believe "Gray's Anatomy" is authority for the statement that as soon as calcification is sufficiently advanced the irruption of the tooth takes place, and I am equally sure Dalton's or Flint's Physiology teaches the same. In the "The American Text-book of Diseases of Children," Dr. Forchheimer says: "The greater part of teething is accomplished before the child is born," and also, "This process of development has taken the whole period of fetal life, so that the child comes into the world with all its teeth fully formed within the jaw." The Doctor has certainly somewhat overstated the facts in the case. I have examined a number of fetuses of the advanced periods, sixth and eighth months, and did not find the teeth in a condition to warrant that statement. In many skulls, embryo and infants, of various degrees of growth, ranging from three months of the former to several years of the latter, I did not find it so. At birth only about three-fourths of the crowns of the central and lateral incisors, and less than half of the crowns of the molars, of the first set, are to be found, the roots being still almost entirely undeveloped. The dentine and enamel of the incisors begin to calcify at the seventeenth week of embryonic life. At birth the roots of the incisors only just begin the process of calcification. Not until three months after birth do the crowns of the cuspids and molars begin to calcify, and the roots of these deciduous teeth are not completely formed and calcified until the twentieth or twenty-second month after birth.

I refer to this particularly, because if the teeth were fully formed at birth and there were nothing needed but a *vis a tergo*, to bring the teeth through the gums, then much of the phenomena observed during teething is not to be accounted for in the way we have usually accounted for it. The aim of this paper is to ascertain what causative relation there exists, if any, between teething and disease in children. I hold that the process of teething includes much more than the mere projection through the gums of previously formed teeth. The generally received view is, that the physiologic process of the development of the teeth, beginning in fetal, is projected on into, and continued in infantile life; so that a considerable part of teeth formation, as well as their irruption, is included in the term dentition. Besides, in regard to the second dentition it is established that while beginning early in embryonic life, much the larger part of it is carried on after birth, and therefore during the first months and years of the infant's existence, we have what I may call the complicated phenomena of the development and perfection of a large part of the first set of teeth, and their irruption, and at the same time a large part of teeth formation of the second set. By the time of

the completion of the irruptive process of the milk teeth, there are also the germs of at least twenty of the permanent ones, in most of which formation is considerably advanced, and calcification already begun.

During the first two years of life a child is building its first teeth, during the first six years it is building its permanent teeth, and attacks of sickness and disease during these first years of childhood can be discovered and affirmed many years afterward by an examination of the teeth, and a near approach to a diagnosis of the nature of the disease and the exact age at the time, can be made. Such complicated phenomena going on after the child has just emerged from its embryonic into its actual life, and continuing during the earliest and tenderest months of its existence, must be a great tax upon the resources of the infantile cosmos. Some one has said: "Woman is an *uterus* with necessary organs and parts associated." With equal aptness, at least, we may define a child as a *mouth*, with necessary parts associated. Dr. White, in the article I have referred to, has shown that the mouth of a child is related and associated by continuity and contiguity to most parts of the entire body. By continuity of its mucous membrane, and especially through its blood and nerve supply it is related to almost the entire organism. The trigemini, the nerve of the mouth and teeth, which is the largest of the cranial nerves—and whose sensory fibers from its posterior root form the semilunar ganglion—receives filaments from some of the plexuses of the great sympathetic (the carotid and the cavernous plexus, connected also with the third and the sixth, and sometimes the fourth, nerves directly, and indirectly with many others), brings the mouth *en rapport* with many different parts of the body. This fifth nerve is somewhat like the par-vagus or a spinal nerve, in the ramifications of its branches, and in its diffused influence and power. It can readily be seen then, that abnormal conditions here, and during the period of dentition, may reveal themselves in localities and parts far removed from the buccal cavity, just as an irritation in the floor of the fourth ventricle may reveal itself in an attack of pseudo-angina pectoris. The connection between teething and diseases in children is nervo-vascular, disturbances of the fifth nerve acting as a producing cause.

The irruption of the teeth, as Dr. White says, is a physiologic and anatomic crisis. Or, as Dr. Love of St. Louis puts it, "In teething the child is passing its first *climacteric*." Physiologic dentition, with normal environment, produces little or no disturbance, perhaps, complicated and exacting as its wonderful phenomena may be. Yet this is not the rule in these modern times. It is a fact that infant mortality is largest during the teething period; more than one-third die during the first year, and about one-half of all children born die during the dentition period. Dentition produces or aggravates the causes of disease. Teeth irruption produces nervous phenomena which increase susceptibility to disease and lessen the power of resistance (White). Impaired nervous equilibrium puts the child in the power of disease, so to speak. Nervo-vascular activity is increased during teething, producing functional derangements, so that a child without or beyond this condition, would tide over a spell of bad weather, for instance, or an attack of indigestion, with little or no disturbance, but during this disturbed equilibrium of the nervous system, as White puts it, these vicissitudes result in

disease. Dentition is physiologic and natural, to be sure, and so are other functions in the human economy, and yet they are disease-producing or superinducing; witness the disturbances during child-bearing and during menopause. And doubtless they may all be produced by similar causes, the disturbed equilibrium of the nervous system or the nervous vascular excitement playing a large part in the etiology of the affections.

I am aware that medical opinions differ somewhat in regard to the place teething occupies as an etiological factor in the diseases of children. A generation or two ago dentition was allowed to play a prominent and solitary part as a cause of disease; today some would deny it any place whatever as a disease-producing factor. The pendulum swings from one extreme to the other, as Dr. Robinson of New York says: "Whenever there is a reaction from an erroneous theory or faulty method of treatment, the reaction is sure to go to an extreme." The truth lies in the middle ground. That teething may stand as a contributing factor in some considerable disturbances to the health functions, initiating abnormal conditions, which, joined and fostered by other factors, result in disease and death, I certainly believe. Ellis, in "Wood's Library, says: "Diarrhea of teething is natural." Thies attributes dental paralysis to the molar teeth. Smith affirms: "Among the most common pathologic results of difficult dentition are certain affections referable to the cerebro-spinal system, eclampsia being one of the admitted results." Smith also lays down the following rule in diagnosis of the etiology of these infantile disturbances: "When similar symptoms arise at each epoch of teething, and subside with the subsidence of the gingival turbulence, teething must be regarded as the cause." Carmichael says: "The evolution of the teeth is one of a number of developmental processes going on in the body, and organs and tissues are prone to disease in proportion to their normal or physiologic activity," and "The nervous system is at these times always in a state of hyperactivity." Speaking more particularly of the philosophy of the connection between teething and those disturbed conditions, Bouchut says: "Convulsions in teething arise from nervous excitement, from pain and disturbance," and who that has had any experience with children can question the assertion? I must set myself down as an advocate of the use of the gum lancet, in suitable cases. If one has ever seen a child in an eclamptic seizure, muscles rigid, eyes rolling, gums tense and inflamed, and has applied his lance, and in a few moments observed the spasm relax and cease, and the child open its eyes in evident relief and ease, it will require no words of mine to convince him that there is still a place and use for his lance in difficult teething. Barrier affirms: "Diarrhea is caused in adults by sudden emotion of grief or fear," and in answer to the question, How? I believe his answer was: "Reflexly and by central nerve irritation." Diarrhea in teething may doubtless be explained in the same way. An aged clergyman, a chaplain, who had attended many executions of murderers, told me that the bladder always emptied itself and that frequently the bowels were influenced in the same way during the last moments. The one philosophy applies to all the different instances.

Teething is no doubt a cause of disease, a superinducing cause at least. It is not sufficient to say

teething is a normal process and will take care of itself. Possibly it would if parents were normal and habits of life were physiologic and hygienic, but in the conditions of modern society prevailing today, and so many babes "brought up on the bottle," of so many of which it may be said with truth, "There is death in the bottle," the slaughter of the innocents goes on by the thousands every year.

If, as I maintain, the complicated and duplicated process of teeth formation is projected from germ into actual life, and the development of the permanent teeth is taxing the powers and resources of the little cosmos at the same time and while the irruption of the just-completed first teeth is taking place surely this is a time when the aid and skill of the well-informed physician may be needed. Little drug medication will be required, the less the better, usually. But first correcting the condition and the habits of the mother herself; keeping away from them the patent nostrums they are made to swallow by the tons in weight every year, superintending their food supply so far as possible, and rendering timely aid during the periods of disturbance as they arrive, infant mortality may be reduced to a much lower percentage than we now have it.

DISCUSSION.

Dr. SLAGLE, Minneapolis—I remember Professor Bell of the University of Louisville saying something that struck me as good philosophy; he said there is nothing easier than for a man, who is smart and well posted, to build up a nice theory, except the facility with which another equally smart man will explain it all away in another way and show up his mistakes. A man who has been in the practice of pediatrics for over forty years and a teacher of pediatrics for fifteen years, is apt to be dogmatic, but the longer I practice among children the less importance I place on teething as a factor in the causation of disease. The medical profession is divided on this subject considerably and possibly will be for some time, still the general trend of the profession is along the line I have been speaking. I believe it is our duty to teach the laity that the symptoms attributed to teething and worms are due to other things. When I am called to a case of eclampsia I will search for every other cause first and then if I can not find any other cause I will look to the teeth, and I will scarify them if necessary. I formerly scarified twenty times where now I scarify once. I want to emphasize that the longer I practice medicine the less stress I lay upon dentition as a factor in the causation of disease except as a predisponent.

Dr. RICHARD, New York—Personally I must endorse the remarks of the last gentleman, or at least, say that it is the belief I have followed for some years and I have not placed a great amount of stress on dentition. We do have to face this as a very common expression among the laity, that the child is teething. I have followed the authorities cited by Dr. Clements, in which dentition is considered coincident with other changes going on in the life of the infant. At the time of the eruption of the teeth I understand there is simultaneously a change in the mucous membrane and the secretory apparatus of the digestive tract, which causes disturbance of digestion. In some cases the disturbance is trivial, in other cases it is serious. I have often used the following illustration: A manufacturing plant which requires a day gang and a night gang, is thrown into more or less confusion as the day gang goes off work and the night gang comes on. There must be more or less disturbance. I feel as if dentition is coincident with these changes, which are going on in the alimentary tract, which are to be looked upon as necessary disturbances and combated when necessary.

Dr. LOUIS FISCHER, New York—I heard part of the paper

only but I should like to be put on record as believing that dentition is a purely physiologic process. I believe with Jacobi and others that all the pathologic changes noted during the period of dentition can easily be accounted for if we will look to their true etiology. I am confident that especially in summer a great many of the diarrheas we see at the various clinics, which the mothers attribute to teething and state that until the teeth come out the diarrhea will not stop, are due to other causes. In winter when we have pertussis or a cough, it will invariably be laid by the laity on these four little teeth. I would like to ask the essayist whether he believes the convulsions during dentition are due to a reflex action, or whether he looks for another cause of these convulsions.

Dr. JOSEPH CLEMENTS, Kansas City, in closing—The criticisms are just what I wanted to get and tried to call out. I have seen the trend in the other extreme. Teething I believe acts as a predisposing cause. I will now speak of convulsions. The other day I was called to see a case of convulsions. A little girl came to my office from about three blocks off and said the baby had fallen out of a chair and was dead. I found the baby in convulsions. I began to look for the cause, looked at the diet, the passages and the bowels and inquired in all directions. I could learn nothing from the mother that would give any light on the subject. I gave the child an emetic and used an enema of hot water, from both of which I got very little result. I then inquired about the teeth and found four molars just breaking through. The mother told me the child had been perfectly well except for the past week it had been peevish and irritable. They did not know what was the matter with the child and thought it was just a bad temper. It seemed to me the teeth had something to do with it. Possibly the diet played a rôle, but there was very little to substantiate that view. I could get scarcely any response from the emetics and little from the enema. The teething I believe may have produced a reflex action through the nervous system and caused the convulsions, just as an irritation in the fourth ventricle may produce pseudo angina pectoris.

SOCIETY PROCEEDINGS.*

The Chicago Society of Internal Medicine.

Regular Meeting, Oct. 19, 1898.

Dr. JOHN A. ROBISON, president, occupied the chair, and after the minutes of the previous meeting were read and approved, Dr. J. M. G. CARTER of Waukegan was elected a member.

Dr. ADOLPH GEHRMANN read a paper entitled

THE RESULTS OF WIDAL'S TEST IN THE DIAGNOSIS OF TYPHOID FEVER FROM DRIED-BLOOD SPECIMENS.

The use of dried blood as a means of collecting and preserving specimens of blood for the diagnosis of typhoid fever, first suggested by Wyatt Johnston in 1896, has been generally used by health authorities as a means of diagnosis since that time. It has been subject to some modifications, but as used in most places it is essentially the same method originally proposed by Dr. Johnston. In Europe dried blood is seldom examined, at least published statements of this use are not to be found. Indeed, Widal's test has been more widely adopted as a public health diagnosis in America and England than it has been on the continent, and in the United States and Canada it has been used to especial advantage. The chief objection to the use of the dried-blood specimen is inability to obtain accurate dilutions, but it may also be said that all the other methods of applying the Widal test require considerable skill for the collection of the serum and the measurement of the dilution, making them, therefore, too complicated for utility in public laboratories.

The most accurate and reliable examinations are those in which, in addition to the other details of technique, some cognizance of the reaction as related to the degree of dilution is taken. In developing the dried blood method various attempts have been made to procure a measured amount of blood at the time of collecting the specimen. The use of the platinum loop, by which drops are collected and deposited separately upon paper or glass and then dried, has been extensively tried.

These dried drops of blood are then units to be followed in making the series of dilutions. We have found that in using the platinum loop in this way there is a possibility of considerable variation in the size of the drop. For instance, the loop may be filled evenly from side to side, or the drop may be almost spherical, bulging out from the loop, and the quantity contained may then be two or three times what it would be if the loop were simply evenly filled. Another method is that in which capillary tubes, as proposed by McFarland, are filled with blood, which is allowed to dry in the tube. The capacity of the tube is known and is as a unit and the dilution is made by crushing the glass in a mortar with a measured quantity of culture or water. In another method the blood is dried and weighed and the dilution calculated from the weight. This method is now used by the Baltimore Health Department. The chief danger in this method is that the serum will separate in drops from the clot that forms and in weighing one may have a greater weight of corpuscles than if the entire mass of blood had dried evenly. When every particle of the dried specimen can be weighed the estimation by this method is very accurate. Considerable blood is also required in order to make weighings. No scheme yet proposed has supplied an easy way of obtaining a definite quantity of the dried blood, at once exact and suitable for the skill of every one. But like many technic examinations, serum diagnosis requires that operators have a thorough acquaintance with the method used. The same result may be obtained by other observers working in another way.

Biberstein has recently deprecated the dried-blood method as impracticable, saying, as the agglutinating substance exists only in the plasma or serum, and as the volume of corpuscles in a given unit of blood, especially in pathologic conditions, varies in a marked degree, it is impossible to procure an accurate unit from which to estimate the dilutions when the corpuscles are present. Further, he holds that the use of attenuated cultures does not facilitate the diagnosis in the dried-blood method. The value of the different methods of conducting the diagnosis can only be determined by the results of a large number of examinations. If such examinations can not, in the main, be shown to be correct, we will have to agree with Kühnau, who concludes that the serum diagnosis requires an exact laboratory study, in which form it is not suitable for general practice. The deductions from the examinations of Johnston, Bloch, Stewart, Westbrook and Wilson and our own series of 109 previously reported results, do not seem to warrant such a limited application. Stewart found in 1000 tests made in Philadelphia, 969 cases correctly diagnosed. In the 31 failures reported the reaction was present three times in cases that were not diagnosed as typhoid, while in 28 it was absent in cases that subsequently proved to be typhoid. In our own series of 109 examinations in 1896, the test failed in 7 instances, the reaction being observed in 5 cases that were not typhoid and being absent in 2 when typhoid was diagnosed. Two of the five cases mentioned, however, presented undoubted histories of having previously had an attack of typhoid fever. The reports of most observers seem to indicate the possibility of a small percentage of failures in making a positive diagnosis, even among those depending entirely upon the examination of the serum, as Comba, Ziemke, Stern and Courmont. They have made the most careful dilutions in series for the different cases that they have examined. Whatever method is used, the failures are due to the absence of the agglutinating substance during the first days of the disease, and on the other hand, to the presence of an unusually strong, normal agglutinating substance.

In regard to the influence of a previous attack of typhoid upon the test, opinions are now giving it less importance because it has been found, by repeated tests after typhoid, that the real reaction of the disease disappears in adults during the first six months after convalescence, and in children somewhat more quickly. (Courmont.) That the reaction does not occur early will be discussed later.

It is admitted that the careful determination of the limits of the reaction, i. e., the dilution in which the normal agglutinating substance is still active, and the degree of dilution in which the specific substance can be shown to be effective in cases of typhoid, must be differentiated. The experiments of Stern, Sklower and Biberstein have fairly demonstrated that a dilution of serum, 1 to 50, entirely removes the danger of observing a normal or pseudo-reaction. As the specific reaction is marked in dilutions much beyond this, it would seem that all danger of mistakes from this cause could be entirely avoided by sufficiently diluting the blood or serum in applying the test. The observation of the limits of the effectiveness of dilutions in producing agglutination is of value in following the progress of a given case, but for the purposes of diagnosis

it is simply desired to establish either the presence or the absence of the phenomenon.

The methods used in the diagnosis of typhoid in the laboratory of the Department are the same as those described by Wynekoop in the "Biennial Report of 1895-96." The specimens of blood are obtained without any special reference to the quantity, it simply being requested that enough blood be sent. The cultures that are used are bouillon cultures made from stock cultures on agar. These bouillon cultures are grown at room temperature, and are used during a period of twenty-four to fifty hours after being planted. The stock cultures are also grown at room temperature. In this way typhoid bacilli are obtained that are not very actively motile, but still are always evenly distributed in the bouillon and show great uniformity in their motility.

In making the test, the dried blood is dissolved in distilled water, and enough water is used to give what would be considered a dilution of from 1 to 15 or 20. It is, however, an estimate and not an accurate dilution. After allowing the water and blood mixture to stand a few moments, so that particles may settle, a drop is taken, with the platinum loop, from the top and mixed with an equal sized drop of bouillon culture. This is placed upon a cover glass in a hanging-drop preparation for microscopic examination. It has been found that the amount of color in the drop is of considerable value in determining whether sufficient dilution is present, and from our experience this is taken into account. The dilution in the first examination is about 1 to 30 or 40. In cases where the reaction seems to be unusually prompt, the original mixture of blood and water is diluted with a drop of distilled water, one drop of the mixture and one drop of distilled water, and this is again mixed with the culture and examined, thus making a further dilution. In typical cases, dilutions may be carried on in this manner three or four times before the reaction disappears. The time of observation is continued to six hours before it is positively reported that no reaction is present. The specimens remain at room temperature, but most of the cases showing the reaction are decided in two hours. In some special cases the dried blood and mica slip is weighed, the blood scraped upon a watch crystal and the piece of mica again weighed, the difference in weight representing the blood solids or about 20 per cent. of the original weight of blood. Distilled water to replace the blood-water is added, and dilutions are made by adding more water in the proportions desired. It has been found that at least 5 milligrams of dried blood are required. This amount can be obtained from five large-sized drops of blood. A pipette, graduated in hundredths of a cubic centimeter, is used for measuring the water or culture in making these dilutions. Prof. Klebs has suggested that all the examinations be made in this way, but so far this does not appear to be an imperative necessity.

From January 1 last to August 1, there were received at the laboratory of the Health Department 340 specimens from suspected typhoids. After some time a letter was sent to the physicians who had sent in the specimens, requesting that they return their opinions as to the final diagnosis or outcome of the cases from the observation of the subsequent clinical course. Two hundred and eighty-three such replies were received and tabulated, with the original date of the blanks accompanying the specimens, and with the results of the tests made with the specimens.

The general summary of this tabulation shows the following result: 340 cases examined, 263 clinical reports returned, 57 not returned, 166 reports of occurrence of typhoid reaction and 174 reports of absence of typhoid reaction were sent. Of the 166 cases in which typhoid reaction occurred, 135 were diagnosed clinically as typhoid, 19 were not clinically reported, 9 were not diagnosed as typhoid, 3 cases passing from observation. Of the 174 cases in which typhoid reaction was absent 37 were diagnosed clinically as typhoid, 38 were not clinically reported, 98 were diagnosed as other conditions and one case passed from observation. The correct diagnoses numbered 233, with 46 failures in diagnosis. The number of times the results have failed to correspond with the clinical reports is large, and should not be taken as evidence of the actual value of the test.

These results are not the results of the examination, of 279 patients, but the simple results of so many tests. From some of the cases reported specimens were sent in several times and, as will be shown, there is reason for the elimination of a number of the failures. The nine cases in which the reaction was present, but which were diagnosed as not typhoid, have the following causes assigned for the sickness: Acute perihepatitis, subacute indigestion, autointoxication from slight uremia, case well three to four days after examination; acute enteric catarrh, influenza, cerebrospinal meningitis, malaria,

enteritis. In none of these was there a record of a previous attack of typhoid. In six of them there was evidence of some intestinal disturbance, as shown by the symptoms enumerated in the blank accompanying the specimen. However, they cannot be explained by offering a doubt as to the diagnosis. We have concluded that they are instances of unusually developed normal agglutinating power. These nine patients were all over 20 years of age, except the last, where the diagnosis of enteritis was returned, a child 6 years of age. The thirty-seven cases where the reaction was absent may be divided into several groups. Fifteen cases seem to be complete failures, as the examinations were made after the first week of sickness, but there were no re-examinations. Nine cases were re-examined and the reaction obtained with the later specimen; in one instance the reaction was absent the sixth but present the eleventh day; another was absent the sixth but present the fifteenth day; another absent the eighth but present the ninth day; and in one of them it was absent the twelfth day but was found on the fourteenth day. There is a possible explanation for two cases in that an interval of five days in one and six in the other occurred between taking the specimen and applying the test. The agglutinating power of dried serum is lost after a time, and the specimens may not have been under favorable conditions to retain this power. In four other cases the blood specimen was too small for a satisfactory test. Among the twenty cases from which the blood specimen was obtained during the first week are two of those in which the blood specimen was small and the two cases in which the examination was delayed; the other two were not in this group. It is possible, then, that twenty-two failures can be explained, but fifteen remained for which there seems to be no explanation. Adding these fifteen to the nine cases of failure in which the reaction was observed, there are twenty-four failures in 279 examinations, or 8.6 per cent. of failures. Further, it is noted that in the group of failures there are three cases of typhoid and pneumonia. The effect upon the reaction in complicated cases of typhoid has not been fully studied. Complications are reported in five cases in the series, that were correctly diagnosed; pneumonia, nephritis and tuberculosis were noted. Ziemke reports cases of pneumonia and tuberculosis where the complicating conditions did not prevent the reaction. It is probable, then, that the failure in these cases is not due to the presence of a complication.

As regards the value of the test in typhoid, it has been shown by numerous published reports of examinations that the results are uniformly positive in well-marked cases of typhoid. If the possible cases of failure, viz., the short duration of the sickness at the time of examination, and the absence of a previous attack of typhoid, can be eliminated, the test becomes an absolute sign. Under general circumstances, however, a single test is simply presumptive evidence. It is clearly not an early sign, no earlier in most cases than the recognized symptoms of typhoid. Frequently, however, the reaction is found early, but in these cases it is sometimes difficult to decide as to the real time of beginning of the sickness, as happens in those patients called walking typhoids. The re-examination is a highly important part of the test and is the only way to increase its reliability. Ziemke reports a case of absence of the reaction on the eighth day but present on the tenth. Biberstein reports the test made on verified typhoid patients: 8 examinations the first week with 2 failures, and 32 examinations the second week with four failures. One case was negative at the first examination, made during the first week, and also negative for the second examination, made the eleventh day, but the reaction was obtained at the third, on the eighteenth day. Another case was negative on the ninth and fourteenth days, but positive on the nineteenth day. These results, which are similar to our own, go to prove the value of re-examinations. In the series of cases showing clinically as typhoid, some had the reaction early; one on the second, eight on the third, four on the fourth, and three on the fifth day.

In the examination of cases that are not typhoid, the absence of the reaction during the first week is only presumptive evidence. Bloch and Bates suggest that those cases in which the test is absent on the tenth day of the sickness should be regarded as not typhoid. Among the failures in obtaining the reaction in our series of examinations, are four tests which were made with blood from cases diagnosed clinically as typhoid: one taken from the tenth day of the sickness two on the twelfth and one on the sixteenth day. One of the cases examined negatively on the twelfth day was positively diagnosed on the fourteenth. Apparently there is no definite time for the appearance of the reaction in typhoid, and the fact that a certain number of days of sickness have passed without the reaction does not necessarily justify the conclusion that the disease is absent.

Dr. GEHRMANN is of the opinion, from the results of the examinations as conducted by the department, and from the expressions of opinions of those practitioners who have availed themselves of it, that it is of considerable value in diagnosis. These facts warrant continuance of the typhoid diagnosis by the department, and for the present at least, the use of dried-blood specimens principally, because of the simplicity of the method. Public health authorities are not obliged to employ the typhoid diagnosis as they are the bacteriologic diagnosis of diphtheria and cholera, because the treatment of typhoid is not conducted by health departments, nor are these patients quarantined. Here in Chicago, however, typhoid has been such an important factor in the health of the city, and has such an influence upon the death records, that every means for the study of the disease should be used and improved. If it can help diagnose the death returns more accurately, and if it can assist in showing changes in mortality from time to time, a better basis is offered for observations as to the effect of sanitary measures introduced to control the disease.

Finally, in view of the 8 per cent. of failures in diagnosis that appear from the department's examinations, these conditions should be considered, which may assist in correcting the results: The directions for obtaining and transmitting specimens must be closely observed, especially as to the drying of the blood. Several examinations of each suspect should be made when the first test does not appear to be conclusive. In the laboratory further dilutions of the blood solution must be made and tested in those cases showing the reaction. In this way normal or pseudo reactions can be eliminated. By closely observing these details, it is highly probable that the test will be more exact and the failures fewer in number.

Dr. J. M. G. CARTER of Waukegan followed with a paper on THE TREATMENT OF TYPHOID FEVER, BASED UPON A STUDY OF SEVENTY CASES.

He drew attention to some thoughts in reference to the treatment, and the resulting conclusions are the outgrowth of his experience. His general experience in the management of typhoid fever was as unsatisfactory as that of many other physicians until he adopted his present line of therapeutics, since which time he has treated seventy cases. His observations before he began the treatment of this series of cases convinced him that the danger in typhoid fever is the pronounced exhaustion present in this disease, which seems to be due to a deterioration or destruction of some of the ultimate cells or tissues of the body, and he believes there is a general consensus of opinion in the profession that this deterioration or destruction is due to the products of the typhoid bacillus. Departures from a scientific line of treatment have been due in the main to a misapprehension of the conditions prevailing in a case of this disease, or in a failure to remember the conditions which should exist in a state of health. The following facts have guided him in an attempt to find a scientific line of treatment: 1. That typhoid fever is a bacterial disease. 2. Typhoid bacilli exist at all times, and in nearly all places, but in varying numbers. 3. Under certain conditions the number or activity of these bacilli, or perhaps both factors, may be increased. 4. The virulence of the disease depends upon the number or activity, or both, of bacilli invading the individual case. A careful consideration of these facts led him to conclude that the treatment of typhoid fever may be reduced to the meeting of three indications, only two of which are always of paramount importance. These are: the maintenance of the patient's strength by proper nutrition; the removal of the cause, and the reduction of temperature.

The determination of what diet is proper in a case of fever is of the utmost importance. He has found very few cases that fare well on beef tea or beef extracts; but usually these foods have produced evil results in his hands. They are heavily charged with uric acid and uric acid compounds, which tend to reduce the alkalinity of the blood (Haig). This may be the cause of the increased obstinacy of the diarrhea in cases fed on beef tea. He condemns the general use of beef tea during the febrile stage of the disease, but it may be given during the defervescence of the fever and in convalescence, with beneficial results in many, if not all, cases. It is his custom to give specific directions as to the amount and kind of food. The food is always prescribed in liquid form and, unless there is some insuperable objection, milk is the universal diet.

The second requirement in the treatment is the removal of the cause. The removal demands first that the introduction of bacilli into the system shall be immediately checked. This is accomplished by sterilizing all food and drink, and by washing the mouth frequently with a solution of boric acid or some other antiseptic. The second requisite toward the removal of the cause is to restore the alimentary canal to its normally aseptic condition.

The third element in this phase of the treatment is to aid the system in its battle with the invading bacteria. The secretions must be assisted, the tissues strengthened and the cells restored. In typhoid fever, even if sufficient nourishment can be given, the enfeebled digestion interferes with its proper preparation and assimilation. Two things can be done: The food may be partially or completely digested, or the native forces of the body may be stimulated and impaired organs strengthened by drugs. Aromatic sulphuric, nitro muriatic or hydrochloric acid may be administered for the purpose of stimulation; and as the heart is the organ most in need of help in this disease, digitalis, strophanthus or caffeine may be given and occasionally, if not generally, small doses of nuxvomica or strychnia may act well to ward off great exhaustion. General tonics are especially needed during convalescence. The reduction of temperature does not always require special attention, but some cases must be treated with antipyretics or some means of reducing fever. He has never used the Brand system. He ordinarily reduces the temperature by means of quinin or some coal tar derivative combined with a heart tonic, usually acetanilid and caffeine; or tepid, cool or cold water is used for sponge bathing. Sometimes he combines these two methods. All cases bear the wet sponging, and most are benefited thereby. Since he has adopted this line of treatment he has treated seventy cases of the disease. These have been of all grades of severity and of various duration. The shortest illness was two weeks, two cases; the longest eight weeks, two cases. The others varied from three to seven weeks, with an average of four and a half weeks. All but one had diarrhea. All had tenderness in the right iliac region or near the umbilicus. Four suffered severe hemorrhages; all but three were delirious. The temperature reached 105 in six cases; 105.75 in one, but usually did not exceed 104.5 degrees F. These high temperatures were seldom present more than one day. The lowest observed temperature occurring as the maximum in any case was 102.5 degrees. All his cases recovered. Before he adopted this line of treatment he averaged about 16 per cent. of deaths in his typhoid cases. He said if he were asked to specify what has caused the reduction of the death rate, and what he believes to be the essential feature of his treatment, he should reply, "abundant nourishment in the form of milk; and the tonics, aromatic sulphuric acid and digitalis." He gives aromatic sulphuric acid and tincture of digitalis combined throughout the entire course of the fever. Sometimes he has continued them a week or ten days after the fever has subsided. These are given from the first, to prevent the heart failure and general exhaustion so common after this disease. The dose varies from five to fifteen drops each every three or four hours, according to the age and condition of the patient and should always be given in water. An abundance of fresh air must be furnished typhoid fever patients.

Of the first fifty-five cases here reported, few were given antipyretics and none the coal-tar preparations. He gave no salol, sulphocarbonate of zinc, salicylate of bismuth or other antiseptic in his treatment of the first fifty-five cases with the exception of aromatic sulphuric acid, and some of the severest forms he has treated are included in that group. Other remedies were given only as were required to meet emergencies as they arise.

To recapitulate: The four most important agents are feeding, sponging, some antiseptic, like aromatic sulphuric acid, and tincture of digitalis or caffeine. A happy result of this treatment is a more rapid convalescence than is secured when feeding is not crowded; but the course of the disease is not abridged in many cases.

Mississippi Valley Medical Association.

Twenty-fourth Annual Meeting, held at Nashville, Tenn., Oct. 11-16, 1898.

(Continued from page 1050.)

SECOND DAY—MORNING SESSION.

Dr. THOMAS CHARLES MARTIN of Cleveland, Ohio, read a paper entitled

COMPLETE INSPECTION OF THE RECTUM BY MEANS OF NEWER MECHANICAL CONTRIVANCES.

The newer mechanical means exhibited consisted of a set of proctoscopes which are provided with obturators of peculiar form, of an illumination apparatus susceptible of adjustment to a number of positions, and of an improvement on the Yale chair, which facilitates the placing of the patient in the knee-chest posture without requiring any movement on the part of the patient after he is properly seated on the chair. The improvement consists essentially of an upholstered board attached

to the left arm of the chair, and a mechanism controlled by a crank and lever, which form a part of the running gear. The anoscope exhibited is an inch and a half (1.27 cm.) in length, and is designed for the inspection of that part of the rectum which is surrounded by the pelvic floor. The proctoscope is four inches (10.16 cm.) long, which the essayist claims is of sufficient length to reach into the inflatable rectum, and is not of so great a length as to obstruct a complete view of the rectal chambers, and yet is of sufficient length to reach the promontory of the sacrum when the pelvic floor is displaced upward by the proctologist's manipulations. Both these instruments are seven-eighths of an inch (2.22 cm.) in diameter; this diameter having been determined upon as the result of calibration in many normal ani. The average diameter of the instrument is equal to the degree of painless expansibility of the anus. The obturators have contracted necks, which constitute these instruments ointment applicators. The middle part of the obturator is channelled, which qualifies the instrument as a nozzle for rectal irrigation; because of its contracted neck the obturator may be used as a self-retaining nozzle. The surface of each obturator is fluted in such a manner that it may be used as a two-way irrigator when properly fixed within its tube. The technique of the inspection is as follows: The patient is required to sit on the chair with his legs crossed and his body facing the knee-board, which is attached to the left arm of the chair. The chair-back is changed to the horizontal by a movement which puts the patient into the Sims posture. The fixed rectum is now examined by means of the short anoscope. After this portion of the rectum is inspected, the chair's lever is extended, its crank turned, and the chair tilted to such an extreme degree of the oblique lateral position that the chair-seat is almost perpendicular and the knee piece, which is a part of the left arm of the chair and against which the patient's knees are pressing, is almost horizontal. Now, at a time when the patient is resting easily in a position which is equivalent to the knee-chest posture, the anoscope is introduced, the obturator withdrawn, and the inspection of the ballooned gut completed. The patient is passively returned to his feet by executing in the reverse order the several steps of this procedure.

Dr. JOHN L. JELKS of Memphis presented a paper having for its subject, "The Relation between the Genito-Urinary Tract and Rectum: the Operations Upon the Female Which Should Receive Priority?" The author champions the assertion that the gynecologist should be as well prepared to remove hemorrhoids and treat an ulcerated rectum as to dissect a cicatrix from the cervix or repair a perineum. The rectal surgeon often finds that, although the rectum is involved to such an extent as to be chiefly complained of, the chief source of danger to the patient is a pus-tube or some other disease. In other words, to relieve the patient and restore her to health and happiness, he must also dissect from the cervix uteri a cicatrix and repair a lacerated perineum. In another case he may be required to sever a urethral stricture.

Dr. WILLIAM B. BRUNS of Deckerville, Ark., read a paper entitled "Rectal Fistula in the Causation of Ischio Rectal Abscess," in which he reported a case with two large pus pockets. He opened the abscess, emptied its cavity, and subsequently did an operation for the removal of the fistula.

Dr. GEORGE D. KAHLO of Indianapolis followed with a contribution on

HYDROTHERAPY IN STOMACH DISEASES.

He said that water is essential to the performance of all physiologic functions; yet its importance as a remedial agent is not so generally recognized. While he does not wish to be understood as opposing entirely the use of drugs in diseases of the stomach, he desires to say that he believes water ranks first among therapeutic resources. It may be used internally as a drink, in lavage as a douche, and as a spray, and externally either applied locally or generally. Its effects, when administered internally depend upon the conditions of the stomach in respect both to taking of food and whether or not there is normal digestion, as also upon the amount and temperature of the water ingested. Cold applications of all kinds are anti-phlogistic, and when prolonged are sedative. They are indicated in acute gastritis and in the control of vomiting and hēmatemesis, but to obtain their full effect it is necessary that their local condition produce an active hyperemia of the skin. Hot applications are useful in the treatment of gastralgia, hyperesthesia, gastric ulcer and chronic gastritis. While he does not ignore the beneficial influences of such agents as diet, exercise, massage and electricity, not to speak of a few of the more important drugs which are thus used, and in obstinate cases especially, physicians are not likely to rely wholly upon any one remedy, however valuable. To be successful, hydrotherapy, like all other forms of treatment, has for its govern-

ing factors an exact diagnosis, a thorough knowledge of the patient, a full understanding of the causative influence and a clear conception of the effects of the remedial agent. To this must be added the confidence and co-operation of the patient.

SECOND DAY—AFTERNOON SESSION.

Dr. THOMAS HUNT STUCKY of Louisville read a paper on "Auto-Intoxication of Intestinal Origin." In referring to the clinical aspects of abscess of the liver, he called attention to the essentials in diagnosis, and dwelt upon the history of the disease. He reported three cases. Of these the diagnosis was confirmed in two by postmortem; in the other by aspiration. In all three the abscesses were chronic when they came under his observation. In only one of the cases was there a history of dysentery, although in one case scars of healed ulcers were found in the large intestines. In these cases he finds the enlargement of the liver is upward. Hoover has made a diagnosis of abscess of the liver from a friction sound in the axillary line between the eighth and tenth ribs. The essayist has not heard this sound in any of his cases, but this should be borne in mind when making an examination in this region. Two of the cases reported were mistaken for malaria. This mistake can be avoided by the more general use of blood examinations. The absence of plasmodium would settle this at once.

Dr. J. C. MORFIT of St. Louis read a paper on "The Importance of Early Diagnosis in Surgical Cases." The diagnosis of a disease ought to be the most attractive feature in the practice of medicine or surgery. It is the foundation on which any plan of treatment is applied. The physician should promptly and exhaustively weigh every indication of cause and effect, and apply his therapy accordingly. He has recently seen two cases of pyosalpinx which were cured by surgical interference. Both had been treated by good practitioners, yet neither had made a complete physical examination, and consequently the real trouble was not detected. One was treated for indefinite inflammation of the bowels, the other for malaria. He cites these cases to emphasize the duty of the physician to himself and his patients of utilizing every available means to arrive at an early and positive decision as to what he is treating.

Dr. GEORGE W. JOHNSON of Dunning, Ill., presented an excellent essay on

GONANGIECTOMY AND ORCHIDECTOMY FOR HYPERTROPHIED PROSTATE IN THE AGED.

In this paper he reported five cases, and made a second report on twenty-eight cases previously recorded. After referring at length to the literature of the subject and reporting his cases in detail, Dr. Johnson arrives at the following conclusions:

1. All cases of prostatic hypertrophy should be given at least two weeks of palliative treatment, with rest in bed. This treatment should be regulated according to the conditions.
2. If no relief is had from this line of treatment, a thorough and systematic examination should be made for vesical calculi and polypi, as well as structural and malignant disease of the prostate and bladder. Cystitis, acute prostatitis, and prostatic abscess should always be borne in mind. The urine should be frequently examined. In cases of cystitis the uterus should be catheterized to determine the condition of the kidneys. This can now be easily done by the Harris instrument. If by digital examination per rectum the prostate is found to be enlarged, its approximate dimensions should be noted and urethral measurements taken. The patient should then be as well prepared as possible for operation. Having decided upon operative interference, the operator alone must decide upon what operation he will do. Gonangiectomy or orchidectomy offers less risk to life.
3. Chloroform should be used, as it requires less time and is not so irritating to the kidneys. The operation should consume as little time as possible. Gonangiectomy or orchidectomy can be done quicker and with less shock than any other operation. Strict attention should be given to the after-treatment.
4. The time for relief after operation is irregular. In his experience the relief has not been as clearly defined as to hours and days, nor as immediate as in most cases reported. In but two cases has the catheter been required after operation. Enuresis was constantly present in his cases, for from one to six weeks after operation.
5. More immediate relief is given to cases of orchidectomy, and the prostate grows softer and diminishes more rapidly in such cases than where gonangiectomy is done.
6. The kidneys should be carefully watched and supported after operation. Mental symptoms appeared in three of his cases, two of which were due to renal disease.
7. Long standing and troublesome herniæ can be successfully treated in the aged. He has successfully treated eighty-

four such cases, in none of which has a recurrence taken place up to this time. Of this number, he has encountered the condition of congenital with acquired hernia in six cases. In five of these cases the acquired sac was outside of the congenital one. In one case it was within it.

8. Bassini's operation was resorted to in all but five cases, and in these Fowler's method was used.

9. Cystic degeneration of the testicles was met with in twenty-five cases. These usually had chronic hydrocele also, and were always cases of hernia of long duration.

10. When the intestines occupied the scrotum in large mass, they were returned to the abdominal cavity three or four days before operation. In many cases there were adhesions preventing reduction.

11. Examinations were always made for vesical calculus, but none found.

12. The somatic condition is greatly improved, and when bilateral orchidectomy was done, the patients became obese.

13. A thorough line of palliative treatment of from two to six week's duration, with rest in bed, was given each patient.

14. In cases of herniotomy, the patient was kept in bed from three to five weeks, unless very asthenic, with the hope of getting better organic union and thereby minimizing liability to recurrence.

THIRD DAY—MORNING SESSION.

Dr. GEORGE BEN JOHNSTON of Richmond, Va., delivered the Address on Surgery. His subject was "The Progress of Renal Surgery." Renal surgery is altogether a matter of the past three decades, having had its commencement with the successful nephrectomy performed by Simon in 1869. Dr. Johnston dealt with nephrectomy; floating and movable kidney; renal and ureteral calculi; neoplasms of the kidney; tuberculosis of the kidney, which when not a part of a general miliary tuberculosis, may have its origin in the kidney, or may be an ascending affection from the bladder. Hydronephrosis also received attention. He made no attempt to arrive with anything approaching completeness at the progress or present status of surgery of the kidney. He endeavored merely to point out some of the advances which have been made in this field of surgery, and to indicate the present views of surgeons upon some of the most important points. Especially did he emphasize the conservatism which has developed along that line, and which now marks the attitude of the surgeon, in this as in other branches—a conservatism which realizes that the glory of surgery is not in amputation and in mutilation, but in saving important organs.

Dr. WILLIAM R. PRYOR of New York City presented a paper entitled "Why I Perform Vaginal Ablation in Pelvic Inflammatory Cases." He stated why, when he performs hysterectomy in such cases, he prefers the vaginal route. He dealt with the subject under the respective heads: incision; separation of adhesions; direction of effort in the enucleation; hemostasis; drainage; hernia; accidents; instruments; narcosis and time; convalescence and results.

Up to October of this year he had performed vaginal hysterectomy for pelvic inflammatory lesions, exclusive of fibroids and cancer, eighty times. Since that time he has made the operation a number of times. No case has died, either from the operation or from complications. He has no fecal fistulae to report, no sinuses, no vesico-vaginal fistulae, and no hernias. There have been no cases of phlebitis and no intestinal obstructions. The vagina has in no case been shortened. For the technique of the operation he refers to the *American Journal of Obstetrics*, Vol. xxxviii, No. 6, 1898.

Dr. SHELBY C. CARSON of Greensboro, Ala., presented "A Consideration of the Limit to Operative Gynecology," the purpose of which was to emphasize the importance of medical gynecology; to show that surgery can not advance a legitimate claim to even the larger portion of this great field. A beautiful tribute is paid to this branch of medicine by applying to it the eloquent eulogy of Daniel Webster upon justice. Surgery as a science is pronounced as practically without limit, but as an art it has probably reached the summit. What constitutes true surgery is then discussed, the author quoting not only from text-books, but from the latest utterances of such men as Wyeth and Annandale, proving that surgery, of all other branches, is based upon principles, and hedged in by fixed laws; that when these are disregarded there is no true surgery. The folly of the ablation of the ovaries and tubes in many cases is made manifest. The nerve element in woman is closely considered, the anatomic connection between the nervous system and the genitalia being defined. As a consequence, neurasthenia is a frequent result, for which surgery affords no relief.

Dr. J. WESLEY BOVER of Washington, D. C., discussed

THE THERAPEUTIC VALUE OF LEAVING LARGE QUANTITIES OF NORMAL SALT SOLUTION IN THE ABDOMEN.

He reports six cases to illustrate the usefulness of this procedure. In a number of cases the effect was not so marked, and in a few but little benefit was apparent. The first case was one of papillomatous broad ligament cyst; fifteen liters normal salt solution left in abdomen; marked increase in urine. The second case was one of large multiple uterine fibroma, and large ventral hernia; secondary operation; three liters normal salt solution in abdominal cavity and one liter under breast, with marked urinary increase. The third case was one of papillomatous fibro-adenocystoma of right broad ligament; eight liters normal salt solution left in abdomen; considerable urinary increase. The fourth case was one of multilocular ovarian cyst; 5000 c.c. normal salt solution left in abdomen; increased excretion of urine. The fifth case was one of multiple fibroma of the uterus and pelvic adhesions; great shock; two liters of normal salt solution left in abdomen; increased urinary excretion. The sixth was one of multilocular cartilaginous cystoma of left ovary; seven liters normal salt solution left in abdomen; excretion nearly doubled during the following six days.

The marked stimulating effect of the remedy on the kidneys is noticeable in all these cases. Penrose has found that the average amount of urine excreted during the first twenty-four hours after operation in 100 cases was 13.4 ounces; for the second, 14.6 ounces, and for the third, 19.8 ounces. He also found that for the first day the maximum amount of urine was 27 ounces. In many of the cases of the essayist this maximum was much more than doubled. While the number of cases in which he has used these large quantities of normal salt solution is small, the effect should encourage a further application of the remedy in proper cases. Not one evil result of the solution was observed in any of the cases.

Dr. F. F. BRYAN of Georgetown, Ky., read a paper entitled "A Plea for Pelvic Cellulitis and Peritonitis." He reported twenty cases, and drew the following conclusions: 1, Cellulitis and peritonitis are important manifestations leading to the greatest amount of suffering that woman is heir to; 2, their recognition and the retention of their nomenclature should keep physicians constantly on the watch for them; 3, their proper treatment in the early stages will obviate these latter evils to a great extent, as cellulitis and peritonitis are easily curable in the early acute stages; 4, that, should opportunity for an early cure not be offered, then the chronic cases should have the medical and minor gynecologic treatment mentioned by him, under which many will be cured, others obtain relief, and a respectable quota will of necessity have to turn to surgery for their cure.

(To be continued.)

Cincinnati Academy of Medicine.

Regular Meeting, October 24.

Dr. HORACE WHITACRE presented a patient with chronic tetanus. There was no history of injury, nor could physical examination find any source of irritation. The principal symptoms were stiffness of the muscles of the neck, especially the sterno-cleido-mastoid; inability to fully open the jaws; and pain involving the jaws. The trouble had lasted about a week. There was no fever. There was no history of taking medicine for any purpose, so that strychnia poisoning could be safely excluded.

Dr. C. R. HOLMES presented a patient from whom he had eight days previously removed a piece of steel that had flown from a hammer, penetrated the cornea of the left eye, the iris, the lens, and lodged in the vitreous in the neighborhood of the optic disc. He had made an incision about a quarter of an inch long, downward and inward, half of the incision in the lowest part of the cornea the other half in the contiguous part of the sclera; the lips of this incision had been retracted, and the ocular electric magnet plunged into the vitreous. The first attempt failed, but on withdrawing the magnet a second time the small piece of iron was found sticking to the magnet. He had made the incision a large one so that the foreign body would run no danger of being brushed off in withdrawing the magnet. Though the incision was necessarily made through the ciliary region, healing had occurred without the least infection. The traumatic cataract formed he intended to remove at some future time. In this connection Dr. Holmes reported two other cases of foreign body in the vitreous. One, in which a piece of copper was the offending body, was removed through a large sclero-corneal incision with a pair of mouse-toothed forceps, the foreign body kept constantly in sight by the

reflected light of the ordinary forehead mirror; the second attempt succeeded in catching the bit of copper and withdrawing it. The traumatic cataract formed was subsequently removed, and now the patient has perfect sight, with proper glass. The third case was a pin that had penetrated the sclera, all underlying structures of the globe, and finally the sclera posteriorly. The head of the pin was seen sticking out from the external wound and was readily withdrawn. There were no sequelæ.

Dr. RICKETTS reported a case of myoma of the left broad ligament, which had been growing rapidly for a number of years. He had used a Langdon rectal tube thrown around the pedicle to stop hemorrhage, and with this as an aid enucleation was comparatively easy and quickly effected. The specimen weighed sixty-five pounds. The primary incision was from the ensiform cartilage to the symphysis. As the woman had only been operated on that day it was too early to say as to the ultimate outcome. The time of operation was fifty-eight minutes.

Dr. HENRY BETTMAN presented a specimen of pachymeningitis hemorrhagica interna; cause unknown. There was also found in this patient profuse hemorrhage in the colon. He also presented a specimen of fibrinous pericarditis, cor villosum, not on account of the rarity of the specimen, but that a diagnosis had been made of fibrinous pericarditis, lobar pneumonia, and pleurisy with effusion all on the left side and just a few hours before death, all of which points were borne out by the findings of the postmortem table.

Dr. JOHN E. GREWE presented a paper on "The Pathologic Anatomy of Syphilis of the Spinal Cord." Numerous illustrations and microscopic sections added much to the value of the paper.

Denver and Arapahoe Medical Society.

Regular Meeting, Oct. 25, 1898.

Dr. J. N. HALL read a paper on

ACUTE PNEUMONIA

and reported sixty-nine cases of acute lobar pneumonia which he has treated in the non-mountainous regions of Colorado since 1893. He has excluded from this number all cases of broncho-pneumonia, tubercle pneumonia, typhoid and hypostatic pneumonia, and all pneumonias resulting from trauma. He tabulated all his cases as follows: Males, 42; females, 20; babies, 7; involvement of right lung 41; left lung 25; both lungs 2, one was not noted; involvement of the whole of right lung, 2; whole of left, 3; right lower lobe or lower and middle, 31; left upper lobe, 5; left lower, 17; both lower, 1; all of right and lower lobe of left, 1. Fatal results, 15, or 21.7 per cent. Nine died on the sixth or seventh day, five from the third to fifth day; 1 on the ninth day. Direct cause of death: Probably diphtheria, 1; neglect and exposure, 2; delirium tremens, 1, and exhaustion, notably of the heart, in the others. In one case edema of the same lung which set in on the fifth day directly contributed to the fatal termination. Two cases were abortive, one in a man of 70, and the other a boy of 7 years; in both cases the disease was cut short on the third day. In two families, three cases appeared in succession, and one patient nursed a fatal case of pneumonia during the preceding week. The janitor of a school, who complained much of the irritating effect of the dust arising from sweeping, suffered two attacks six months apart. Another case, a boy of 15 years, who swept a schoolhouse, suffered from an attack. In six cases the disease occurred as tubercular patients, but none of them were tubercular pneumonia. In one case resolution was delayed for six weeks. Three cases known to have been addicted to use of alcohol all died, one of which developed delirium tremens. Profuse expectoration of clear blood occurred in one case. Of the 69 cases, 9 occurred during the first five years of life, with one death; 8 during the second five years, with 1 death; 8 during the second decade, all recovering; 11 during the third decade with 4 deaths; 10 in the fourth with 2 deaths; 8 in the fifth with 4 deaths; 5 in the sixth with 2 deaths; 2 in the seventh with 1 death; and 4 in the eighth decade all recovering. The highest temperature recorded was 106.4 degrees, in a fatal case, a boy of 2 years, and 105.9 degrees in a boy of 7 years, who recovered. One case occurred suddenly and with great severity while the patient was at a ranch, far from help. In two cases the sick one was alone, and delirium coming on early, he was unable to feed himself or keep up fire. One of these, emerging from his delirium on the second morning, crawled to the stable and loosened all the horses,

turned on the windmill that they might not suffer for water and crawled back to his hut to await his doom, since it was twenty-three miles to town.

In conclusion: The known frequency of pneumococcus in the sputum rendered the occurrence of three attacks of pneumonia in two sweepers of schoolhouses of great interest, for one can not but suspect that the dust of the schoolroom must generally contain pathogenic germs. The study of these cases offers us reason for thinking that pneumonia is materially different from the disease in any other region between us and the Atlantic.

Dr. WHITNEY, in discussing Dr. Hall's paper, dwelt upon the difficulty of diagnosing cases of lobar pneumonia in the aged and children, in both of whom the pathognomonic signs of initial chill, rusty sputum and crepitant râle are, as a rule, absent. He lays great stress, from a diagnostic standpoint, upon bronchial respiration and dullness occurring in the same lung. He fully agrees with Dr. Hall that pneumonia is not more fatal in Denver than in any other part of the country. He called attention to a statement made by a German physician that he had not lost a single case out of some seventy cases of pneumonia. He gives his patients salicylate of sodium from the start, 10 grams every hour for twelve hours, none for the next twelve hours, and then resumes the treatment. Dr. Whitney expects to apply this treatment in the next favorable case.

Dr. SPIVAK reported a case of typhoid fever, which showed on the fifth day after admission to the hospital, unmistakable signs of pneumonia. He acted upon the suggestion of Dr. Whitney, and all the signs had disappeared on the following day. He gave, however, only 7 grams of salicylate of sodium every three hours. He continued the treatment, 5 grams t.i.d. and the patient made a perfect recovery after a somewhat tedious right phlebitis.

Dr. JAYNE said that the somewhat greater mortality in mountainous regions is due to the fact that the patients are either not taken care of, or are subjected to great exposure during transportation to town or hospital.

Dr. C. K. FLEMING read a paper on

THE ABUSE OF THE MECHANICAL TREATMENT OF UTERINE DISEASES.

He said: "A question that is frequently put by the physician to one engaged in practice of gynecology is: 'What is the reason that there seem to be more pelvic diseases in women than formerly?' In reply, I have been obliged to state that I believe that the increase of pelvic diseases is due, in a large measure, to the abuse of the mechanical treatment of uterine diseases." He drew the following conclusions:

1. The vaginal speculum is capable, through lack of asepsis, of carrying infection into the vagina and thence to the uterus.
2. The uterine sound should have no place in the armamentarium of the general practitioner.
3. The results from intra-uterine medication are, to say the least, unsatisfactory, and may be decidedly harmful.
4. The rapid dilatation of the cervical canal is the ideal method, but the operation should be performed in the home of the patient or in the hospital.
5. The uterine curette should never be used in the office.
6. Pessaries are useful only in the treatment of displacements, are only palliative, and should not be used unless radical means are refused.

Dr. JAYNE accorded with the statements of Dr. Fleming, and said that since the gynecologists have become skilful in bimanual manipulations the use of the sound is superfluous. He very seldom uses it, and only in cases where its introduction would be of absolute diagnostic value. When sterilization is impossible, he dips the sound in pure carbolic acid and washes off with bichlorid solution. He has seen many cases where a pessary produced perfect and permanent reposition of the uterus.

Dr. STOVER said that the specialists have so much encroached upon the general practitioner that the tongue depressor will sooner or later be deemed a dangerous instrument except in the hands of an otologist.

Dr. SPIVAK was in perfect accord with the general statements of Dr. Fleming, but thought the introductory remarks of the speaker somewhat misleading, as one would be liable to conclude that the increase of pelvic trouble in the female, if there is an increase, is due to the slovenly ways of the general practitioner. He thinks the general practitioners, especially of the last decade, are fully impressed with the theory of asepsis, and that they practice what they have been taught. He thinks that the syringe nozzle used by women indiscriminately before they ever consult a physician is in many cases a hot-bed of infection.

PRACTICAL NOTES.

Collodium Bandages.—These are recommended by Schliep for hernia of the umbilicus, and other hernias in which ether spray proves ineffective. A thin pad of cotton three or four inches square, is dipped in the collodium and applied with gentle pressure.—*Munich Med. Woch.*, September 27.

Sodium Salicylate in Facial Paralysis.—Catrin reports a case of severe facial paralysis following an attack of acute articular rheumatism three months previously, which he cured in twenty-three days with 74 grams of sodium salicylate without electricity or massage.—*Semaine Méd.*, October 12.

Edema of the Eyelids.—Dechamp announced at the recent French Congress of Ophthalmology that he had been very successful in curing essential edema of the eyelids with Lannelongue's injection of 1 to 20 zinc chlorid, once a week for six to eight weeks.

Puncture of the Colon in Typhoid Fever.—The *Semaine Méd.* of October 12 reports the favorable result of puncturing the transverse colon in a case of typhoid fever. It was so enormously distended that it had displaced the heart and threatened immediate cardiac collapse. The introduction of a small trocar allowed the escape of the gases, and all the threatening symptoms subsided at once.

New Collateral Route.—The creation of a new collateral route for the blood of the portal vein in cases of cirrhosis of the liver has been successfully accomplished by S. Talma, who sutured the large omentum and gall-bladder to the abdominal wall, and latter the dilated spleen in one case, a boy of 9 years. Two years have since passed, and the normal coloration of feces and urine and the absence of icterus show that the liver is performing its function well, although it is and always will be much indurated. The lad seems perfectly healthy.—*Semaine Méd.*, September 28.

Local Anesthesia from Blood Expulsion.—S. Kofmann writes to the *Cbl. f. Chir.* of October 8 that he was at first much pleased with the success of Obert's improved local anesthesia (*JOURNAL* xxx, page 736), but discovered later, to his surprise, that the anesthesia was complete without the cocain. Driving out the blood had alone accomplished the result. He describes several operations on the foot and lower arm, including an osteomyelitis of the fibula, during which the patient experienced no pain except from the tightness of the ligature. After the ligature is applied a certain interval must elapse, as with the Oberst method, before the anesthesia becomes complete.

Curettement in Pharyngeal Catarrh.—A. Malherbes describes in the *Rev. de Laryng.* October 1, his complete success in curing seven cases of chronic posterior pharyngeal catarrh by curetting the nasopharynx, in ethyl bromid anesthesia, the patient lying on a table with his shoulders at the edge and the head hanging in forced extension. The infected masses drop into the mouth or nasal passages, whence they are removed with hot boricated irrigation. Quite an effort is required to dislodge the hard masses sometimes encountered. He applies, a week later, a tampon of cotton moistened with iodine 1 gram, potassium iodid 3 grams, aq. dest. 40 grams. With this exception he abstains from douches, sprays and other local applications. All his cases have been permanently cured (eight to nine months), and the voice has returned to normal.

Treatment of Varices.—Excision of the veins and the ablation of a large cutaneous flap in the leg, has been found very satisfactory in treatment of varices by E. Schwartz, who has performed the operation on fifteen patients, all permanently cured, the wound healing by primary union. The elasticity of the skin is such that it can be sutured together after the removal of the spindle-shaped flap extending the entire length of the inner side of the leg, 5 to 6 cm. wide at the widest part, and

it will stretch to form a natural elastic stocking sure to hold the veins of the leg firmly in place. If there is an ulcer the flap should include it. The patient is kept in bed three weeks, the leg raised on a cushion. His patients have all resumed difficult occupations, as washerwomen, carpenters, etc., and the ultimate results have been perfect.—*Presse Méd.*, September 7.

The Physiologic Dressing.—Augè and Casteret have been testing sodium bicarbonate, recommended by the Russians, and find it fully as effective as antiseptics in dressing suppurating wounds, and in many cases more so. It promotes epidermization much more rapidly, suppresses pain and inflammation in from twenty-four to forty-eight hours; dries up the suppuration rapidly, favors the secretions by cleansing the pores, while increasing phagocytosis and restoring the alkalinity to the blood. This latter they consider so vital that they assert that the resistance of the organism to infections is proportionate to the alkalinity of the blood, and that the effect of artificial serum is due to this cause. They have tested the bicarbonate on a number of suppurating gangrenous wounds, panaris, phlegmonous abscesses and dermatoses, and they conclude their very favorable report with the remark that the still unattained ideal dressing would be one which killed the microbes like the antiseptics—which the bicarbonate does not—while still respecting the integrity of the cells.—*Presse Méd.*, September 18.

Ocular Affections of Utero-Ovarian Origin.—In ocular affections connected with utero-ovarian trouble—which are more frequent than usually supposed—Professor Mooren relieves the tenacious hyperesthesia of the retina with the following: Potassium bromid 4 grams, lupulin 6.5 grams, pulv. rhubarb 1.5 grams, extract of centaurea, q. s. Make into 120 pills. Take three pills three times a day. If the ovary is the cause of the ocular troubles he gives: Atropin sulphate 3 centigrams; licorice powder 2.5 grams; extract of licorice q. s. Make sixty pills. Take three pills a day. If the reflex ocular irritation depends upon some simple functional disturbance in the uterus or ovaries he administers Paracelsus' elixir in the dose of two half teaspoonfuls a day for several weeks, in the case of robust patients, otherwise reducing this amount to a quarter teaspoonful, or merely several drops during the few days preceding the menses. A copious metrorrhagia may induce a serous effusion in the retina, or a neuro-retinitis, which are relieved by cold compress or ice to the back of the neck, with leeches to the mastoid epiphyses and saline purgatives, if necessary. Local treatment to remove the cause in all cases.—*Semaine Méd.*, September 28.

Modern Treatment of an Infection.—Professor Grasset observes that this treatment is based upon the principle that we can not attack the microbe directly, but must direct all our energies to stimulate and augment the spontaneous resistance of the organism. He rejects serum treatment, except for diphtheria, also antiseptic, "as internal antiseptics is extremely difficult to realize and can only be exceptionally accomplished, and also antithermics, as they are useless and even dangerous in the treatment of infective diseases, except in certain rare and well-defined cases. His treatment is therefore restricted to: 1. The régime, stimulating, tonic. 2. Blood-letting, white and red, that is, venesection and diuretics, sudorifics and purgatives. 3. Water in every form and at all temperatures, baths, lotions, injections, drinks, etc. Water acts as a stimulant and diuretic. The cold bath benefits less by the effect on the temperature than by facilitating the elimination and oxidation of the toxins, stimulating the organism and soothing the nervous symptoms. 4. Injections of salt solution, or artificial serum, which have a three-fold therapeutic effect. They stimulate and remove the arterial hypotension and protect against anemia, while they also help to eliminate the toxins and at the same time produce unmistakable reactional phenomena.—*Progrès Méd.*, September 24.

Journal of the American Medical Association
PUBLISHED WEEKLY.

SUBSCRIPTION PRICE, INCLUDING POSTAGE:

Per Annum, in Advance	\$ 5.00
Foreign Postage	2 00
Single Copies	10 Cents

In requesting change of address, give old as well as new location.

Subscriptions may begin at any time and be sent to

THE JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION
No. 61 Market Street (Occidental Bldgs.), Chicago, Illinois.

MEMBERSHIP IN THE AMERICAN MEDICAL ASSOCIATION.

This is obtainable, at any time, by a member of any State or local Medical Society which is entitled to send delegates to the Association. All that is necessary is for the applicant to write to the Treasurer of the Association, Dr. Henry P. Newman, 100 Washington St., Chicago, Ill., sending him a certificate or statement that the applicant is in good standing in his own Society, signed by the President and Secretary of said Society. Attendance as a delegate at an annual meeting of the Association is not necessary to obtain membership.

On receipt of the subscription the weekly JOURNAL of the Association will be forwarded regularly.

Gentlemen already members of the Association should send their annual subscription to the Treasurer, or direct to the JOURNAL office.

All communications and manuscript of whatever character, intended for publication in the JOURNAL, should be addressed to the Editor, and all communications relative to the business of the JOURNAL, proof-sheets returned, or in regard to subscriptions, should be addressed to THE JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION, 61 Market Street (Occidental Buildings), Chicago.

Original communications are only received with the understanding that they are exclusively contributed to this JOURNAL.

SATURDAY, NOVEMBER 5, 1898.

THE MICROBE OF CONTAGIOUS PLEURO-PNEUMONIA.

The essential lesion of contagious pleuro-pneumonia of cattle (a peripneumonia of the French) consists in the distention of the interlobular connective tissue spaces by a large quantity of inflammatory exudate. If a drop of this serum is inoculated into the subcutaneous tissue there will appear, after from nine to twenty five days, an inflammatory engorgement of varying dimensions, which is often followed by death. At the autopsy there is found a large quantity of yellowish serum in the tissue spaces, which is here and there coagulated into gelatinous masses. The exudation sometimes amounts to several liters. Animals that recover after a slight sickness of a few days become refractory to experimental inoculation as well as to natural contagion.

This fluid, so virulent for animals of the bovine species, is without action upon other species. These facts were, according to NOCARD and ROUX,¹ demonstrated by WILLEMS in 1850.

The demonstration of the specific microbe of pleuro-pneumonia, its isolation and cultivation, would constitute a very desirable progress. Heretofore all attempts, in innumerable ways, in that direction have failed.

The introduction of collodion sacs for the purpose of cultivating microbes in the living body, such as was practiced by METCHNIKOFF, ROUX and SALEMENI, in their study of the toxin and antitoxin of cholera, appears to have been a very happy idea. The wall of

collodion constitutes a perfect barrier to the microbes, as well as to the cells. The microbes may multiply in the interior of the sac, because they are protected from the phagocytes. On the other hand, this wall is permeable to fluids and substances dissolved in them, forming a perfect osmotic membrane. In this way poisonous substances produced by the bacteria pass outward, so that the microbic auto-intoxication does not take place, and, finally, the substances in the serum of the animal used may enter the sac.

NOCARD and ROUX employed such sacs in the study of the microbe of pleuro-pneumonia, inoculating the bouillon which they contained with a trace of the serum of pleuro-pneumonia and then inserting the sacs into the peritoneal cavity of rabbits. In from fifteen to twenty days the sacs were found to contain an opalescent fluid, slightly albuminous, which contained, neither cells nor microbes that would grow on the ordinary media. With a magnification of 2000 diameters and a very strong light, a great quantity of very small mobile points were seen, of such minuteness that it was difficult to say, even after staining, what their exact form could be. No such bodies occurred in the fluid of a sac of collodion, inserted in the same manner without having been inoculated with the pleuro-pneumonic exudate. Sub-cultures of the fluid of the first sac gave exactly similar results. Incubating rabbits, which become emaciated, may die before the day fixed for the autopsy. The blood of the organs of such rabbits failed to give any growths of bacteria after inoculation upon various media and even into collodion sacs. Death resulted—in all probability an intoxication due to outward diffusion of the products of the microbe. Here is a new example of an animal being very susceptible to the toxins of a microbe to which it is insusceptible.

Collodion sacs, inoculated in the same way as described and inserted into the peritoneum of guinea-pigs, did not give any growths. Hence, it may be concluded that it concerned a special micro-organism, which multiplied in successive cultures in the medium produced by osmotic changes in the interior of the fluid in the collodion sac inserted into the rabbit's peritoneal cavity. This micro-organism was found by successive inoculations into cattle to be the virulent agent of pleuro-pneumonia.

Subsequently it was found possible to cultivate this microbe outside the abdomen of the rabbit by inoculating sterilized bouillon which had been allowed to remain in the peritoneal cavity of a cow or of a rabbit in collodion sacs for several weeks. Then the bouillon acquired the properties necessary for the growth of the pleuro-pneumonic microbe in the test-tube; further experiments showed that the addition of four drops of the serum of the rabbit or of the cow to 5 c.c. of a solution of peptone² rendered this also

¹ Le microbe de la péripneumonie; Annales de l'Institut Pasteur, xii, 1896, p. 240.

² As recommended by Martin, Annales de l'Institut Pasteur, 12, January, 1898.

a suitable culture-medium, so that it is now possible to cultivate the microbe of pleuro-pneumonia in the ordinary way. It will now be possible to study its toxin and make attempts to modify its virulence.

These extremely interesting observations point the way in which it may be possible to study certain other diseases, the specific microbe of which have not yet been isolated. It is very interesting also to note that NOCARD and ROUX have brought into prominence a micro-organism of such minuteness that the ultimate limits of our present means of magnification have practically been reached. Really the final criterion of the presence and multiplication of a micro-organism in the cultures described is furnished by inoculations.

TYPHOID WITH PROMINENT RENAL SYMPTOMS.

While typhoid fever presents many distinct types, as afebrile, ambulatory, abortive, hemorrhagic, and qualifying adjectives of this kind are a positive aid to the student, attempts at such classification as pneumo-typhoid, nephrotyphoid, and names of like character, can not but make the subject extremely intricate, even when they are manifestly designed to indicate the organ or system upon which the brunt of the attack is falling. It were better then to speak, not of nephrotyphoid, but of typhoid with prominent renal symptoms. This variety is not uncommon, as a review of many recent reports of typhoid will show. The renal complications may occur at the height of the disease, when no particular trouble in diagnosis occurs, or nephritis may occur as a sequela. Occasionally, as in a case reported by WILSON, a primary attack apparently involves the kidneys only, an acute nephritis of typhoid origin, if we may so use the term, the intestinal symptoms being completely masked by those of the urinary. Usually, in this class of cases, a relapse occurs, in which the abdominal typhoidal symptoms become in their turn prominent, the kidneys, strangely enough, suffering but little. Even when a relapse does not occur, the Widal test will remain the deciding factor, and it might be stated here that in every case of acute nephritis, the agglutination reaction should be carefully employed for the following reasons: While, as a rule, the diets of nephritic and typhoid patients are the same, yet it must be admitted that many good practitioners allow their nephritic patients fruits and even occasionally a little solid food. When it comes to the question of drugs it can be readily seen that a positive diagnosis is of the utmost importance; for while on the one hand, in nephritic cases, calomel and the saline cathartics are unquestionably indicated, on the other, in typhoid, such remedies would in many instances work great harm, causing perhaps a perforation of the bowel, severe hemorrhage, or both. As regards the care of the excreta a point of considerable practical interest is presented. When the diagnosis of

typhoid nephritis is made, the urine and feces are promptly subjected to the action of disinfectants as in all typhoid cases; but suppose the diagnosis to be made merely of acute nephritis with the typhoid origin undiscovered; naturally, in such a case, no efforts at disinfection are made, and one might readily imagine another Plymouth, Pa., experience.

The symptoms of an ordinary acute nephritis may greatly resemble a typhoid at the onset. The onset of nephritis may be gradual (though usually sudden) and accompanied by severe headache, pain in the back and limbs, nausea and vomiting, a slight fever, pallor of the skin, and perhaps a slight edema of the eyelids, the only distinctive feature being the urinary changes, diminution of the amount of urine even to total suppression, high specific gravity, presence of large amounts of albumin, and microscopically, casts, epithelial and blood. If it were not for the Widal test it might be totally impossible to diagnose a co-existing typhoid until perhaps the rose-colored eruption, blood in the stools or the symptoms of possible perforation suddenly opened our eyes. Yet another difficulty presents itself: In the early stages of typhoid, the agglutination reaction is not in evidence, often appearing only after the characteristic temperature curve, the eruption, and other abdominal symptoms have practically settled the diagnosis. It behooves us then to always bear in mind that in all cases of typhoid infection, a negative result to the serum test in the early stages of the disease will not warrant us in concluding that the reaction will not occur later on or that the disease under consideration is not typhoid. The practical point in all this is that in all cases of nephritis it must always be remembered that no matter how apparently clear the etiologic factors may be, there is always a danger of coincident typhoid, and we should be on our guard not only not to institute treatment which would be deleterious to a possible enteric fever, but to also adopt measures tending to the prevention of the spread of the disease.

MALARIAL AFFECTIONS OF THE EYE.

It seems strange when one considers the vast amount of space given to rare ophthalmoscopic affections in the various text-books on the eye that but little or no room is allotted to the effects of the plasmodium malarie on this most important structure. Possibly this is on account of a natural hesitancy to report or describe, as malarial, eye affections in which no blood examination has been made; possibly it is because the observers have not looked upon the malaria as the exciting cause. Among the external eye diseases depending upon the malarial parasite, probably a serpiginous ulcer of the cornea is the most common. Phlyctenular keratitis also occurs, and occasionally a herpetic eruption involving the upper lid and supra-orbital region; indeed the two latter conditions may co-exist. These affections have all occurred

in the experience of the writer and, in all of them, an examination of the fresh blood revealed the presence of the plasmodium.

YARR, in the *British Medical Journal* of September 24, in his article on "Malarial Affections of the Eye," states that tropical practitioners are continually on the watch for ocular manifestations which experience has taught them are characteristic of malaria, cases "with characteristic symptoms, characteristic ophthalmoscopic symptoms, and above all characteristic pathology." He thinks that all ocular troubles the result of malarial infection have their starting-point in disturbances of circulation, and classifies them under the heads of neuritis, hemorrhage into the retina, retino-choroiditis, and effusions into the vitreous. YARR has given a most complete record of neuritic symptoms, symptoms that will readily distinguish the malarial neuritis from all other forms, and includes the following: The sufferer as a rule has had several attacks of paludism previous to the onset of the present symptoms. At the beginning of his ocular trouble complaint is made of supra-orbital neuralgia and great aversion to light; night blindness is also present. Perception for colors is not reduced unless complete atrophy supervenes. One of the most characteristic symptoms, according to YARR, is the great diminution of visual acuity, its sudden increase on the ingestion of quinin, and a perhaps subsequent fall even under the influence of that drug. The ophthalmoscopic examination reveals "swelling of the papilla, which assumes a greyish red color, edema of the circumpapillary retina, with effacement of the papillary margins, and enlarged and tortuous veins." In over 30 per cent. of the cases, he describes small retinal hemorrhages confined for the most part to the periphery. One symptom, due to the presence of the plasmodia within the capillaries, "peculiar coloration of the papilla, *tiente rouge-grisâtre*," is said to be pathognomonic. In conclusion it is stated "about 80 per cent. of cases terminate in a partial atrophy, indicated by varying diminution of visual acuity, irregular contraction of the field, and slight greyishness of the disc; many end in apparently complete recovery; some rare cases go on to complete atrophy." The affection is usually binocular. Under retinal hemorrhage two chief varieties are described; the small peripheral and the large peripapillary, in which the former are by far the more common; indeed YARR suggests that probably many of the slight interferences of sight that occur in ague are due to these minute punctiform hemorrhages associated with edematous retinae. The large hemorrhages are most liable to be present in those afflicted with pernicious fever, in the stage of so-called malarial cachexia, and may be so large as to result in immediate and total abolition of sight. In about one-fifth of all the intermittent fevers, there develops an edema of the retinal structures which as a rule promptly subsides and ul-

timately completely disappears with the cessation of the disease. Occasionally, however, the process continues, involves the deeper ocular tunic, and the inevitable contraction of the new-formed connective tissue brings about an atrophic condition of retina, choroid and disc. Under effusions into the vitreous, YARR mentions a condition in which a peculiar whitish reflex is observed when the reflected light is used. This, it is thought, is due to serous infiltration into the vitreous, superinduced by paludism; in one case reported it certainly responded to the administration of quinin. Among the occasional ocular diseases due to malarial poisoning may be mentioned periodic blue vision, central scotoma, sudden and persistent amaurosis, and amaurosis ending in atrophy. In conclusion YARR warns the oculist to always bear in mind that amaurosis may be caused by the quinin which the patient is taking, a blindness of several days even being due occasionally to this cause.

THE COMPULSORY NOTIFICATION OF VENEREAL DISEASES.

It may be stated as a general hygienic principle, that is, one in regard to which medical authorities are generally agreed, that compulsory notification of infectious diseases is an indispensable adjunct to the medical defense of the public from their ravages. The public itself, with its dread of these maladies, far greater than that felt by the physician himself, falls in readily with the idea, and endures and imposes inconveniences none the less serious because they are voluntarily assumed. This is true as regards some disorders at the present time that were not long since hardly reckoned as seriously infectious, and which were consequently allowed to propagate themselves freely, in many communities at least. It is probable, or at least possible, that the number of disorders that will be held as reportable is by no means complete, and that with our increasing knowledge of germs and their action in producing disease, we will come to consider it necessary perhaps to demand isolation and full sanitary precautions in many disorders now considered harmless as regards contagion or infection. The medical and lay public are both passing through an educational stage in this regard, and the tendencies of the former, or a large and influential part of it, are decidedly on the advance in this respect at the present time.

A recent item of news from Germany stated in effect that an ordinance had been passed requiring physicians to report as infectious diseases all cases of venereal disease, when such could be done, in their opinion, without detriment to important interests. The leaving of the matter thus to private judgment must practically emasculate the law, but that does not affect the fact of the recognition of the principle that these affections ought in the interest of the public health to be reported. It is, when stated baldly, a

little odd that disorders, one of which is not only directly contagious by personal contact, but may also be communicated by intermediaries, clothing, drinking-vessels, etc., as well as transmitted to offspring, and that has as its consequence some of the most serious disorders to which mankind is liable, and another that, according to the latest view, is responsible for a very large proportion of the special disorders of the female sex, should not only be not subject to compulsory notification, but should, of all others, be most strictly protected by law. If violations of medical confidence are likely to be anywhere followed by exemplary legal punishment, it is in just these cases, where the peril to the community and to individuals is overlooked as compared with the effects of revelations of what are assumed to be disreputable facts. The result is innumerable innocent victims by marriage and otherwise, and if we are to accept the estimates of some specialists as to the prevalence of gonorrhea in the male population of our cities, and consider them in connection with the views of modern gynecologists as to the evil effects of this disease, conjugally acquired, upon female health, the risks an innocent girl runs in marriage seem formidable enough to warrant almost any legal restrictions to meet the evil. The laws that only compel one quasi-criminal class of female unfortunates to submit to legal regulations, while possibly of some utility in military garrisons, have not proved their efficiency in the defense of the general public, and their success in any case is disputed and disputable.

Whether a law requiring compulsory notification would be practicable for all these cases is perhaps open to question; that it would be evaded to a considerable extent may be assumed as certain. The liability to heavy penalties and damages for non-reporting would probably strengthen the law and make it more effective. The record might even be only a temporary one, the physicians' reports being filed alphabetically and destroyed after a certificate of recovery. In any case they could be kept as it were confidential, and reference to them allowed only under pledges of secrecy and for thoroughly valid reasons. Under such conditions compulsory notification of venereal diseases might be to a certain extent a public protection, at least a partial safeguard against infection of the innocent. How far the German regulation will be effective is another question, and a rather more dubious one.

At the present time our health boards require notification of only a few acute infectious diseases, but there are chronic ones equally infectious and hardly less deserving inclusion in such a list. It is true that as a rule they are less immediately dangerous to human life, but they are many of them more repulsive and ultimately as fatal. Leprosy is one of these about which there is no question whatever; the need of its isolation is clear, and yet there are lepers going

about in our large cities, pursuing ordinary avocations and constantly coming into contact with others who may receive their contagion. The danger from this disorder, however, is infinitesimal in comparison to that from the multitudes who carry about with them the infection of syphilis, which is innocently acquired, it is safe to say, a hundred times more frequently than is that of leprosy, and which has in it possibilities of evil hardly less than those of the other more dreaded disorder. It is a matter certainly of interest that the principle of its sanitary control by legal notification has been recognized as well as that of the hardly less formidable gonorrhea, and the further development of the idea will be worth observing. As physicians we can not be indifferent to a measure which, whether fully practicable or not, is yet an effort in the right direction. The compulsory notification of these diseases, if it can be practically carried out and thoroughly enforced, ought to be as a sanitary measure free from the objections to the older registration laws that apply to only a limited portion of one sex, while it should be a still more efficient aid to public sanitation and incidentally also to better morals.

WHY SHOULD WE ESTIMATE FOR UREA?

We have been taught that the excretion of uric acid to urea stands in the relation of 1 to 33. HAIG states "My researches have extended over a large part of the last twelve years, but taking only the figures of the longer periods of my estimation of my own excretion, we get a total of 2351 days, in which 28,447 gr. of uric acid, 805,432 gr. of urea and 127,725 of acid (reckoned as oxalic acid) were excreted, giving a relation of uric acid to urea of about 1 to 28, and a relation of acid to urea of 1 to 6.3."

If we desire to estimate the amount of uric acid in a given sample of urine, and turn to the process first devised by HOPKINS, we might be astounded at the lengthened process necessary to obtain the amount of such a common ingredient as uric acid. Indeed, the quantitative estimation is hardly ever resorted to at the present day, on account of its tediousness and certain errors which might ensue from the expertness required in making the estimation. The simple quantitative method of precipitating the uric acid by acidulating the urine with hydrochloric acid and collecting on an equipoised filter is also open to serious and fallacious results. Therefore, it saves time and trouble to say that the daily excretion of uric acid to urea stands in the relation of 1 to 33 and, after estimating the amount of urea, it is an easy matter to compute the amount of uric acid excreted daily in a given quantity of urine.

The specific gravity method is also simple in estimating the amount of urea. For instance, a method is given which states that: "A given specimen of urine, neither albuminous nor saccharin, containing a normal

proportion of chlorids, and having a specific gravity of 1020-4 is a quantity of 1500 c.c. (50 oz.) in twenty-four hours, may be taken as a standard normal specimen containing 2 to 2.5 per cent. of urea. These conditions being observed, a higher specific gravity would indicate an increased proportion, and a lower a diminished proportion. Under these circumstances, a specific gravity of 1014 indicates about 1 per cent. of urea and of 1028 to 1030 about 3 per cent." Here again there is room for unbounded fallacy.

But what of the more accurate methods for the estimation of urea, as now taught by the foremost medical colleges? DAVY's method, which depends upon the decomposition of urea by means of sodium hypochlorite, has certain objections, because it is stated that NaClO in the presence of caustic alkalies causes the evolution of only one-half of the nitrogen of urea, the remainder being retained as a cyanate. With the KJELDAHL method the writer has had no experience. The method, however, which seems to be the favorite is that known as the "hypobromite," and depends upon the decomposition of the urea in the urine by means of sodium hypobromite (NaBrO), with the production of sodium bromid (NaBr), water, carbon dioxid (CO_2) and the evolution of nitrogen. After correcting for temperature and barometric pressure, the nitrogen in the hypobromite method can probably be most accurately estimated. Suppose that we have before us a given specimen of urine and we desire to find the amount of urea by the hypobromite method and, after completing the examination in detail, we find the amount of urea present in this given specimen. It is true, we have at last obtained the correct data in regard to the amount of urea in the urine, but it is also true that we have not determined the amount of metabolic activity nor the amount of animal food eaten the day before by the patient, and upon these factors depends the average normal amount of urea in the urine. Therefore it is hard to devise a *standard* normal amount of urea, because it varies with katabolism and with the amount of animal food giving a great amount of urea, and vice versa.

What is the normal amount of urea excreted by man? MUSSER states that the average daily amount of urea excreted by an adult in the twenty-four hours is about 500 grains. According to VON JAKSCH it is from 496 to 620 grains. PURDY places it at 512.4 grains; NEUBAUER and VOGEL from 387 to 620 grains; TYSON from 310 to 620 grains. SIMON states the case very explicitly when he says: "The amount of urea is well illustrated by comparing the condition of the poorly nourished North German laboring population with that of the well-fed merchants, the excretion of urea in the former amounting only to from 271 to 519 grains of urea and in the latter to 465 or 620 grains." A careful review of this subject therefore discloses the fact that the average daily

amount of urea excreted by man varies from 271 grains (SIMON) to 630 grains—the maximum amount designated by other writers. Since the normal amount of urea in the urine depends upon katabolic activity and upon the amount of nitrogenous food ingested, and since this normal amount is so variable, we may well ask of what real benefit is the estimation of urea in the urine?

THE ARMY MEDICAL DEPARTMENT OF MANILA.

Reports recently received at the Surgeon-General's office from Manila, Philippine Islands, from Lieut.-Colonel HENRY LIPPINCOTT, chief surgeon, Department of the Pacific, give a view of the condition of medical affairs at this far-away military station. As yet the men of this command have undergone none of the fatal experiences of the troops in the home camps. Typhoid fever existed in Camps Merriam and Merritt, San Francisco, Cal., which they occupied prior to their embarkation, but the infected men were left behind in the field hospital at the Presidio. The troops were necessarily closely packed on shipboard during the long voyage, but they had distilled water to drink and, instead of the sinks which spread the infection in our insanitary camps, they had latrines flushed by a constant stream of sea water. The disease was thus held in abeyance, but we may expect to hear in progress of time of the development and spread of typhoid fever among them unless medical and military officers profit by our experiences in this quarter of the globe and take especial care of the sanitation of their barracks and quarters. It is interesting to remark that the landing of supplies from the transports through the surf at Cavité and Camp Dewey was as difficult and dangerous as the landing at Daiquiri and Siboney, and that heavy rains fell constantly during active operations in the Philippines as in Cuba, yet although the troops, at the date of Colonel LIPPINCOTT's dispatches, had been ashore at Manila for as long a period as the Fifth Corps stayed in the vicinity of Santiago, and had been subjected to some hard field service in their attack upon the Spanish lines, there had been no such breakdown of the health of the men as occurred in General SHAFTER's command. This alone demonstrates that there were were climatic conditions and local infections in the one case that were not present in the other, and goes far to answer the question which has been put so often recently: Who is responsible?

The number of deaths from disease and accidents since the first fleet sailed from San Francisco (May 25) has been only 29, with 14 of which typhoid fever is credited. The other items in the bill of mortality are: Pneumonia 3, dysentery 2, meningitis 3, and 1 each from septicemia, paralysis, cardiac rheumatism, endocarditis, appendicitis, insolation and morphin poisoning (suicide). This for over three months in a command of 18,000 men is equivalent to an annual

rate of only 6.44 per 1000, which would be considered an excellent record for troops well cared for in good barracks in times of peace.

The lists of battle casualties show that 11 men were killed and 12 officers and 104 men wounded, 1 officer and 7 men dying from the effects of their wounds. In the attack on Manila, August 13, the field hospitals were not moved forward, as Camp Dewey was only four and a half miles from the scene of action. All the wounded were dressed and comfortably in bed by 7 P.M. of the day of the attack. No amputation was considered necessary, although there were some severe wounds complicated with fracture of the limbs. The field hospitals were removed from Camp Dewey, August 17, to the Spanish military hospital in Manila. This hospital is in fair repair and has room for 400 patients. Prior to placing our people in the wards the woodwork was cleaned and thoroughly disinfected. It is probable that some of the sick at Cavite will be transported to this establishment.

During the voyage to Manila Colonel LIPPINCOTT prepared a circular for the guidance of medical officers and typewritten copies bearing the approval of the commanding general, were issued before the attack. The instructions thus conveyed proved of great value at a time when the conditions are said to have been most trying. It is officially reported that the Surgeon-General may well be proud of the field and hospital work of the volunteer medical officers.

The health of the command is stated to be fairly good, although the sick list is larger than it would be were the troops better situated in a sanitary way. They are all quartered in buildings; some are well housed, others are not. There is a great tendency to stomachic and intestinal troubles referred to the difficulty in restraining the men from eating and drinking unwholesome articles. Dysentery is common and malarial fevers are of frequent occurrence.

CORRESPONDENCE.

Judge Kohlsaas and the Probate Court.

CHICAGO, Oct. 31, 1898.

To the Editor:—Some of the statements which have appeared in the medical press of late criticising the official acts of Judge Kohlsaas appear very strange to the thousands of citizens of Chicago who have known him, as has the writer, for twenty years or more. His reputation as lawyer and judge is so very different from that sought to be given him by the critics, that the thought at once arises that there must be a mistake somewhere. If it were a fact that Judge Kohlsaas habitually, or even occasionally, ruled differently in regard to physicians from his rulings with others, that fact alone would show his unfitness for the bench, and not only physicians but others should unite to secure his defeat. The writer, having waited in vain for some one to make reply to these criticisms, and thinking it due to the profession that they should be informed if these things are so, has undertaken a somewhat hurried investigation on his own account and desires to publish his results and conclusions. And believing it but just that Judge

Kohlsaas should have the opportunity to be heard in his own behalf, the writer addressed a note to him in which he asked him if it were a fact that he as a judge ruled that he "would not in any case allow more than one bill for medical services to be collected against an estate in his court," and that he would not allow more than \$2 per visit to a physician under any circumstances." Judge Kohlsaas's reply is certainly sufficiently explicit on these points. After stating that these criticisms had been called to his attention, but that he had not thought them worthy of notice, he says: "I answer the statements you quote categorically." "I have not stated, nor have I held that I would not allow more than one physician's bill against an estate." "The claim is too ridiculous for consideration." "The records of the court utterly refute the charge." "I suppose I did refuse some doctor's bill in some particular case, owing to the circumstances of that case, but I do not recall any one such case." "No such general line of action has ever suggested itself to me." "As to the other matter, i. e., that I will not allow to exceed \$2 per visit, I can only appeal to the record, in which the statement is contradicted a hundred times." "Both of these allegations are the malignant offspring of some disgruntled claimant who makes no allowance for the particular facts in the case as they appeared to the court at the time, or the harassing and oppressing duties of the probate court in this county." "Any one acquainted with the working of the court here will know that the constant and imperative effort of the court is necessary in order to make the administration expenses as small as possible. To do this in the great volume of business, requires almost infinite patience and diligence. Lawyers, doctors, administrators, executors, guardians and undertakers have often taken exception to what seemed just to the court. Certainly any one of these classes has just as much reason to complain as have the physicians."

It so happened that Dr. M. P. Hatfield of this city was the first one to whom the writer spoke about this matter, and he at once said that in one case coming under his personal knowledge, a case in which he had been called to give testimony as to the value of medical services, \$3 per visit had been allowed by Judge Kohlsaas.

Personal examination of the docket of the probate court shows incontrovertibly that Judge Kohlsaas's statements are correct. Running through the records of November, 1897, far enough back to be of unmistakable value, we find, as can any one who chooses to make the examination, numerous cases where more than one physician was allowed to collect from the same estate, and where more than \$2 per visit was allowed. A few instances only will be quoted. Both Dr. W. K. Harrison and Dr. E. J. George were allowed their bills for services against the same estate, the former being allowed his charge of \$2 per visit in all cases but one, in which a charge of \$3 was allowed. Drs. St. John, Loring, Warren and Butler were allowed bills aggregating five hundred and fifty-odd dollars against the estate of Peter Roes, two of the charges being consultations at \$25 each. One of these bills was reduced from the claim as presented, but the aggregate allowed was as stated above. Dr. A. V. Hutchinson was allowed \$2, \$3 and \$4 a visit. Dr. P. H. Matthei was allowed \$3 per visit, and Dr. J. S. Mitchell \$3 per visit and \$2 for office consultation. These examples could apparently be multiplied indefinitely were not this sufficient.

The writer has no particular concern that Judge Kohlsaas should be re-elected, and would not object to any fair and honest means brought to bear to prevent his re-election, but he does resent that any one should attempt under false pretenses to use the intelligent medical profession to further a personal grudge or to pull political chestnuts out of the fire.

Respectfully,

HORACE M. STARKEY, M.D.

Judge Kohlsaat Defended.

CHICAGO, Oct. 31, 1898.

To the Editor:—Your issue of Oct. 8, 1898, contains a letter from Dr. D. H. Galloway in which it is made to appear that Judge Kohlsaat refuses to allow: 1, more than one physician's bill against an estate; and 2, more than two dollars per visit, no matter what the service may have been.

Here are a few facts found in the records of the Probate Court, available to the whole world and ready to the hand of the most casual inquirer:

Estate of Sarah A. Toohy. Docket 43, p. 274. Claims allowed Nov. 22, 1897: Dr. D. R. Brower \$153. Dr. Jas. H. Etheridge \$200.

Estate of Daniel Butters. Docket 42, p. 230. Claims allowed May 25, 1897: Dr. Frank Billings \$100. Dr. R. D. MacArthur \$354. Dr. Jos. M. Patton \$150.

Estate of Jos. T. Torrence. Docket 43, p. 151. Claims allowed Dec. 31, 1896: Dr. John H. Chew \$25. Dr. A. H. Cooke \$25. Dr. Frank Billings \$50. Dr. R. R. Campbell \$325. Dr. R. D. MacArthur \$2,385.

The humor of Dr. Galloway's letter lies in the fact that there are hundreds of similar illustrations to be had by merely opening a book.

As to the "two dollar a visit" statement consider the following:

Estate of Isabella L. Dunning. Docket 48, p. 148. Oct. 24, 1898. Allowed: Albert B. Strong, M.D., five dollars a visit.

Estate of Daniel Butters. Docket 42, p. 230. May 25, 1897. Allowed: Dr. Frank Billings, seven visits, \$100.

Estate of Edwin Partridge. Docket 41, p. 196. July 22, 1896. Allowed: Dr. E. O. F. Roler \$10 for a night visit.

Illustrations similar to the foregoing exist score upon score, and these are cited for information of physicians, most of whom are interested.

PHILIP CLARKSON.

1009 Ashland Block.

Chloroform and Gaslight Intoxication.

200 OAKWOOD BOUL., CHICAGO, Oct. 25, 1898.

To the Editor:—A note under the above title, in the *JOURNAL* of October 22, suggests a degree of ignorance or carelessness on the part of the doctors responsible for the occurrence, which I hope is, but may not be, entirely absent from the profession in this country. At any rate, it seems to me to be of sufficient importance to justify a further notice. The case is as follows: A patient was anesthetized with chloroform in the presence of a gaslight. The narcosis lasted three hours and during that time the doctors and nurse experienced a spasmodic cough. Patient died in six hours, the nurse in twenty-four hours and the doctor was "at the point of death" for two or three days. The fatal results were attributed to the inhalation of the fumes produced from the combustion of the vapor of chloroform in the gas jet. The products of the combustion of chloroform are chlorin and hydrochloric and carbonic acid.

There is a very simple way of overcoming this difficulty and one which I have very frequently employed with entirely satisfactory results. This consists in accompanying the vapor of chloroform with the vapor of ammonia; the latter neutralizes the noxious gases, producing the chlorid and carbonate of ammonium, which are entirely innocuous in the quantity produced. This may be accomplished by pouring a little ammonia water on a piece of gauze or a towel and waving it in the air occasionally or hanging it up near the gas and replenishing the ammonia from time to time. So little is required that the odor of ammonia is scarcely noticeable.

A few months ago I wrote to a firm and suggested that this fact be stated in their price list, where so many useful facts are given, and they replied that the enormous quantity of chloroform vapor present in some operating-rooms made this

impracticable if not impossible; that the amount of ammonia necessary would make the room uninhabitable. I have repeatedly used this method and have never had any bad effects and indeed none present has ever complained of any inconvenience from either the ammonia or the chloroform and sometimes the operators did not know that any such procedure was being carried out.

A surgeon told me that he performed an operation in one of Chicago's hospitals, which lasted a little over an hour and that during the operation the anæsthetizer administered to the patient, the attendants and the air of the room *eight ounces* of chloroform. The only remedy for such a condition would be to get another anæsthetizer.

If this suggestion is borne in mind when giving chloroform at night, there need not be any more deaths from chloroform and gaslight intoxication.

Yours very truly,

D. H. GALLOWAY, M.D.

Chairman's Address of the Section on Neurology.

ST. LOUIS, Mo., Oct. 25, 1898.

To the Editor:—When I began to get my address ready for my quarterly in order to place it for future reference, I sent galley proof to the secretary of the Section. The paper has been printed, but three months after the meeting at Denver.

I did as I have done heretofore, having no desire to antedate the *JOURNAL*, but being absent over three months with a sick wife, did not know that you had not published it. You can do as you please about abstract, but I do not think Section work will appear as complete as the ASSOCIATION would desire for future reference with only abstracts of president's addresses.

If you print only as an abstract kindly put this in your correspondence column, as I wish to go on record with the explanation and gentle protest, my gentle and amiable friend.

I do not think you are wise in excluding any address for the good of the ASSOCIATION, no matter what authors may do with them as to other journals, especially the quarterlies.

If you decide to publish only an abstract kindly say where the full text may be found, but, if you do, please record my kick. . . .

Very truly yours,

C. H. HUGHES, M.D.

ANSWER:—The full text of Professor Hughes' article may be read in Brother Hughes' valuable journal, the *Atienist and Neurologist* of July, 1898. We regret extremely that the good brother could not wait until the publication of the other papers of the Section on Neurology in the *JOURNAL*, but having decided otherwise, our Chairman's address necessarily falls under the rule.

The Proposed Medical Examiners' Bill.

CHICAGO, Oct. 28, 1898.

To the Editor:—In the October issue of the *Chicago Medical Recorder*, there appears a report of some remarks I made at a recent meeting of the Chicago Medical Society, in reference to the proposed "Medical Examiners' Bill" for Illinois. The report simply contains my objection, and makes no mention of the remedy I suggested for the evil pointed out. I happen to know that this omission is not the fault of the stenographer. For this reason I ask the *JOURNAL* to privilege me with a few remarks on the proposed bill.

This Medical Bill, originated and prepared by physicians, is accordingly *pro bono publico*, i. e., for the purpose of excluding from the practice of medicine all persons not educationally fitted according to orthodox ideas. This is a laudable purpose and a child of a good principle. But the promoters of the proposed bill, as it now stands, are so generous that they propose to secure the purpose of the bill by the sacrifice of another good principle, viz: a strict adherence to principle, or the preservation of personal identity, while homeopaths, eclectics and

regulars all have more or less recognition by the intelligent laity. They certainly differ very materially in the principles of internal medicine, which is surely a very important matter, so that, for regulars to officially endorse homeopaths and homeopaths to endorse regulars, as will practically be the case with this proposed Board of Examiners, we will have an exhibition of acknowledged bankruptcy of medical principles, because to the physician, the focal point of all medical knowledge is therapeutics. It is proposed that opposites shall officially endorse and recommend opposites to public favor! Now, my suggestion, made to the Chicago Medical Society, was that the avowed object of the proposed bill would be secured by the several schools simply co-operating along the lines common to all, and which would include everything in the usual medical curriculum, excepting internal therapeutics. This would preserve self-respect all around, while the diploma of a "recognized" medical college, which is to be a prerequisite for admission to the State's examination, would be a reasonable guarantee of qualification in internal therapeutics. That other States have omitted this feature can not be an argument for the same fault in Illinois, unless it is good reasoning to say that because others have been weak and foolish we should be weak and foolish also. Men holding opposing principles can and should respect each other's honesty of opinions, and for the very same reason they can not afford to unnecessarily compromise their principles, especially their professional principles, for any purpose whatever. "High potencies" are either correct or they are monstrous mockeries.

Respectfully, J. SANDERSON CHRISTISON, M.D.

Conservative Treatment of Intestinal Occlusion by Internal Electricity.

CHICAGO, Oct. 31, 1898.

To the Editor:—The above caption is the title of a very interesting paper by R. P. Johnson, M.D., in the JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION, Oct. 22, 1898.

It is not the purpose of this reply to criticise adversely the idea or method of treatment set forth in said article. There are, however, one or two points to which I wish especially to call attention.

1. The method and manner of application embodied in the paper is the same as that given to the medical profession by M. Boudet of Paris eighteen or twenty years ago, and subsequently by Dr. M. A. Cleaves of New York, and others. As the essayist quotes quite extensively from Dr. Larat, I take it, from the quotations used, that he refers to Dr. Larat's article on "Intestinal Occlusion Treated by Electricity," in "Bigelow's International System of Electro-Therapeutics," which also gives a very good account of Boudet's efforts and experiments, as well as a clever description of his electrode and the salt solution used by him. Consequently he must be more or less familiar with these facts and, therefore, I think, should have given Boudet at least a little credit for his original work and untiring efforts. Dr. Larat also states that it was Duchenne who first directed attention to the treatment of obstruction of the bowels and habitual constipation by means of electricity, and as he used the faradic current almost exclusively in his experiments, physicians as a rule have had recourse to the same current. However, in 1876, Leroy d'Etiolles observed that smooth muscles were not affected by faradic excitations, and that, on the contrary, they are the most powerful in causing contraction of striated muscles. Later, Boudet insisted on this same distinction, basing his conclusions not so much on the cases he had successfully treated by electric injections as on the physiologic observations made by experiments on animals. He also observed that to give the intestines a galvanic current of sufficient intensity and duration to produce the desired effect with the metallic electrode, there was great danger of causing an eschar of the

mucous membrane. To avoid this, he invented an electrode which consisted of a gum tube, with holes in the side, supplied with a hollow metallic mandrin to which could be attached a fountain syringe and binding-post for fastening the battery cord. He used a salt solution for the injection, and the galvanic current, which he interrupted every half minute.

2. To use the author's electrode, as directed in his paper, the mandrin, which is exposed to the salt injection, will become corroded, and the oxychlorid of the metal of which it is made set free and driven into the tissues, a condition which might be undesirable.

3. I understand that the Doctor has patented his electrode. I shall not, in this paper, attempt to discuss *pro* and *con* this phase of the subject, but suffice it to say that such is certainly not in keeping with the "Code." As the method of treatment and similar electrodes have been used for years both in this country and Europe, he surely has no claim to priority, originality, uniqueness or first discovery.

In view of these deductions and facts, and recognizing the importance of electric injections as recommended by Boudet and others in the treatment of intestinal obstruction and habitual constipation, I had constructed for my use by Truax, Greene & Co., Chicago, an electrode which they have seen fit to name "Dr. J. R. Pennington's Colon Electrode," a cut of which is herein represented. It consists of a flexible metallic cable on which is vulcanized india-rubber and, at the distal end

a disc of soluble copper, carbon, zinc, gold or platinum may be attached, according to the purpose for which the electrode is to be used. To the proximal end may be attached a fountain syringe and tip of battery cord. This electrode is enclosed in a smooth, soft-rubber colon tube, so that the current only comes in contact with the mucous surface through an aqueous medium injected through the tube. With this electrode no salt or other solution can come in contact with the flexible mandrin to corrode it, and with it we not only get the combined effect of water and electricity, by which the mucous membrane of the entire bowel is given an electric bath and peristalsis actively stimulated, but because of the variety of discs, one can also carry out indications for cataphoric medication or the diffusion of medicated solutions into the diseased tissues, a method which seems to us might be of some importance in the treatment of enteritis, intestinal catarrh, fermentation, putrefactive conditions and mucous colitis, as well as relieving obstructions of the bowel and habitual constipation.

Columbus Memorial Bldg. J. R. PENNINGTON, M.D.

Separate Cranial Bones.

ADRIAN, MICH., Oct. 25, 1898.

To the Editor:—The case of Dr. Roseberry, reported in the JOURNAL of October 15, reminds me of an almost identical one which occurred in my early practice. Mrs. R. M., of about 30 years, was delivered May 16, 1871, of a full-term child, male and still-born, the bones of whose cranium were completely separated, and feeling, as Dr. R. expressed it, like a bag of bones. This was her second confinement, and the labor was normal and easy, the child weighing six pounds. Her previous child was a strong, healthy male. The woman died a few years subsequently of tuberculosis. I have no further history of the case.

Yours truly, WM. E. JEWETT, M.D.

PUBLIC HEALTH.

Medical Attendance at Theaters.—The Paris *préfet de police* has ordered each theater to make arrangements so that a physician will always be present from the beginning to the end of the performance, and also at the general rehearsals.

Contagiousness of Pneumonia.—The contagiousness of Pneumonia is not generally accepted, but Dumont has observed five cases in forty in which the coincidence was so striking that he considers mild prophylactic measures should be extended to this disease.—*Nord Med.*, October 1.

Health in Chicago.—The Health Department's report for September gives 1780 deaths for the month, a rate of 1.10 per 1000, as compared with 1.04 per 1000 for September, 1897, and 1.02 for September, 1896. The principal causes of death were: Diseases of the nervous system 219, consumption 182, diarrheal disease 155, other acute intestinal diseases 179, heart diseases 96, typhoid fever 65, cancer 63, pneumonia 61, diphtheria and membranous croup 52, bronchitis 49. The deaths of persons under 1 year of age numbered 470 and between 1 and 5 years 232.

Adulteration of Food and Drink.—A writer in the London *Lancet*, August 27, points out the fact that, in these days, the adulterations of food are generally made with substances that are wholesome, or at least not markedly injurious to health. These adulterations, therefore, come under the head of commercial cheats rather than sanitary offenses; they are cheap substitutions rather than poisonous sophistications. Margarin is an excellent food substance, but it is not butter; and wheaten flour is good, but the fact of coloring it with turmeric does not make it mustard. Gooseberry wine, again, is an excellent beverage, but it can not be the smallest degree of truth be called champagne, even though the name has been accepted for years by the public as a synonym for cheap champagne. Lord Palmerston, it is said, once told a deputation of wine merchants who waited on him that there was never a good champagne year in France unless there was a good apple crop in Normandy. We should like to think that this was because the season which was favorable to the production of good grapes was also favorable to the production of good apples. It is also stated that many owners of large pear orchards in France are under contract to send their entire produce to a firm of wine merchants in the champagne district. It is evident, if this be true, that a large section of the public is beguiled into regarding cider, perry and gooseberry wine as champagne. In other words, pears, apples and certain berries evidently afford abundant material for making a very popular, excellent and palatable drink. In spite of this fact people are constantly in pursuit of some fruit-juice beverage. But really good cider, perry and the like are not easy to procure except in the immediate neighborhood of their production. Under the falsely described and tempting title of champagne, however, the public eagerly drinks, smacks its lips and calls it an excellent wine. And thus the immoral traffic in substitution is encouraged and sustained, to the enormous profit of the dealer and greatly to the detriment of the purse of the consumer.

Formaldehyde House Disinfection.—The Schlossmanglyco formol apparatus (*JOURNAL*, xxx, 397) has proved extremely effective at the Mannheim General Hospital, where it has been given a thorough trial. The glycoformol is a solution of formaldehyde solutum, glycerin (to prevent polymerization) and water. It is heated over a spirit lamp inside a ring shaped vessel, in which water is also vaporized. The steam from both passes together into four brass receptacles from which it is forced out at a pressure of half an atmosphere, forming a whirling vapor that sets the entire air of the room in motion, so loose that it is impossible to see an electric light or sunlit window through it. Three hours are sufficient to kill all pos-

sibly accessible germs, even anthrax spores dried on a thread and placed in the toe of a boot or in a slightly opened trousers pocket, but the fumes do not penetrate to the center of a thick mattress in this time, and these are disinfected by impregnating them with 2 per cent. solution of formol. While this apparatus surpasses all others to date in the rapidity and effectiveness of its work, it has the great disadvantage that the pungent odor of the formaldehyde clings to the room for several days, and can not be removed entirely even with ammonia spray, which it is impossible to use on painted surfaces. Rabbits are killed by the glycoformol fumes but are not affected by the fumes from any other apparatus. The apparatus costs eighty marks and is guaranteed to disinfect eighty cubic meters. Czaplewski's experience with it has not been equally satisfactory, and he states that the glycerin leaves a sticky deposit on objects. He also finds that an ordinary steam spray inhaling apparatus will answer the purpose equally well, as the glycerin is unnecessary, the effect depending upon the moisture. With this simple arrangement, similar to Lister's carbolic spray, he secured as good results as others with the Schlossman, spraying 600 to 750 c.c. water to a liter of formalin in an hour, and thus disinfecting a space of fifty cubic meters. The main point is plenty of formaldehyde and plenty of steam in the finest spray. If there is dead air or the surface is already wet, the formaldehyde does not penetrate so effectively.—*Munich Med. Woch.*, October 11.

Tuberculosis in North Carolina.—The bulletin of the State Board of Health contains some striking reflections on the prevalence of tuberculosis in that State. The figures are given as approximate and as an aid to a gradual opening up of the subject. Estimating the population of North Carolina at 2,000,000 and the annual death-rate at 15 per 1000 there are 30,000 deaths in the State annually. The usual proportion of the deaths from tuberculosis to the whole number of deaths is generally agreed to be one in seven. That would make over 4000 persons dying of that disease every year. Previous to death they were of course in the last stage of the disease and, therefore, virulent foci of infection, and should, according to the resolution, be removed to the sanatoria to prevent infection of other members of the family. Taken at this stage very few cures could be hoped for, but owing to scientific care and treatment, many would be carried over to the next year, and the number of this class would therefore be still larger the second. On a basis of 4000 deaths, it would seem to us fair to assume that there are twice as many in the intermediate and incipient stage, and as they hold out a hope of cure they should have the advantages of the sanatoria. So that the total number in sight to be cared for is 12,000. To allow for any exaggeration, let us deduct 33.5 per cent. That would leave 8000. If 25 per cent. of these are able to attend a private institution, 6000 would be left to be cared for by the State. At \$150 per patient, the cost for maintenance would be \$900,000 per annum: counting in interest on plant and incidentals we will call it \$1,000,000, which is about the present total cost of our State government, including its eleemosynary institutions. Everything has to have a beginning, and the outlay at first would be small and the good accomplished proportional, but it is very difficult to make a beginning when the end is far out of sight. If funds were available, say at the rate of \$10,000 per year, the greatest amount of good would doubtless be obtained in such a State as North Carolina by educative measures, and not by the establishment of sanatoria. Unless the public and the lay press, in the future, show a greater alacrity to grasp the importance of the subject, than they have in the past, several years must elapse before radical preventive measures will receive support. By missionary labors from county to county, from hamlet to hamlet, it is probable that ten times as much could be accomplished in preventing the spread of tuberculosis, with the same amount of money, as could be done through sanatoria. God speed every effort to stay the "great white plague," which robs so many of our homes of their loved ones, but let us be sure that our efforts are wisely directed.

BOOK NOTICES.

The Principles and Practice of Hydrotherapy, a Guide to the Application of Water in Disease, for Students and Practitioners of Medicine. By SIMON BARUCH, M.D. With numerous illustrations. Pp. 435. New York: William Wood and Company. 1898.

There is no question that in the general neglect of hydrotherapy the profession deprive themselves of a most valuable therapeutic remedy, and this volume, better than any other with which we are acquainted, systematizes and makes available modern methods of therapeutic use of water.

The work treats of the physiologic effects of water; the anatomy and physiology of the skin; functions of the skin; physical properties of water; rationale of the action of water in health; the effects of hydropathic application upon the distribution and composition of the blood; influence of hydropathic application on the respiration, on the muscular system and temperature; the practice of hydrotherapy; ablution; half bath; affusion; sheet bath; cold rub; wet pack; wet compress; precordial compress; the full bath; the cold full bath; therapeutic indication of the full cold bath; fever; reason for therapeutic supremacy of the cold bath; infectious fever; objections urged against the Brand method; contraindications to the bath; the warm full bath; the continuous or hammock bath; localized continuous baths; the douche; the hip bath; irrigation, lavage, enteroclysis, etc.; steam as a styptic; the internal use of water; therapeutic indications; practical application of hydrotherapy. Then follow indications for its use in certain specified diseases.

Chapter 25 is given up to the discussion and treatment of chronic rheumatism and gout; chapter 26 to the hydropathic prescription, and chapter 27 to a historic summary of the existing state of hydrotherapy in Germany, Italy, France, England and America, concluding with a plea for instruction in hydrotherapy in our colleges and hospitals. The work is timely and we fully commend it, and we are sure of its hearty reception.

The Principles and Practice of Medicine. Designed for the Use of Practitioners and Students of Medicine. By WILLIAM OSLER, M.D. Third edition, entirely revised and enlarged. New York: D. Appleton & Co. Pp. 1181.

This edition has been wholly recast and the arrangement of the sections changed. As in the former edition there are eleven sections, but the titles have been changed as follow:

1. Specific Infectious Diseases.
2. Diseases Due to Animal Parasite.
3. Intoxication and Sunstroke.
4. Constitutional Diseases.
5. Diseases of Digestive System.
6. Diseases of the Respiratory System.
7. Diseases of the Circulatory System.
8. Diseases of the Blood and Ductless Glands.
9. Diseases of the Kidneys.
10. Diseases of the Nervous System.
11. Diseases of the Muscles.

The author states that the following articles have been rewritten or are new, viz.: Vaccination, Beriberi, The Bubonic Plague, Cerebro-Spinal Fever, Pneumonia, Malta, Gonorrheal Infection, Cancer of the Stomach, The Gastric Neuroses, Enteroptosis, The Cirrhoses of the Liver, Jaundice, the Diseases of the Bile-passages, Diseases of the Pancreas, Diseases of the Thymus Gland, Diseases of the Spleen, Lymphatism, Addison's Disease, Encephalitis, Neurasthenia, Erythro-melalgia, and many shorter articles, as Hypertrophic Stenosis of the Pylorus, Ether Pneumonia, Anesthesia, Paralysis, Pneumaturia, Albumosuria, etc.

Into the sections on Typhoid Fever, Tuberculosis, Rheumatic Fever, Diabetes, Gout, Parasitic Diseases, Diseases of the Blood, Heart, Lungs and Kidneys, much new matter has been incorporated. The section on diseases of the nervous

system has been rearranged and an attempt has been made to group the diseases in accordance with the modern conceptions of the anatomy and functions of the parts.

We have little to add to our notice of the second edition (vide JOURNAL, Nov. 30, 1895, page 966). The criticisms then made hold good now, but we regarded the work as one of the ablest contributions to the literature of the subject in this country, an opinion which we still hold.

A Treatise of Diseases of the Ear, Together with a Brief Sketch of the Anatomy and Physiology of This Organ. By ALBERT H. BUCK, M.D. Third revised edition. Pp., 592. New York: William Wood and Company. 1898.

The present tendency to eliminate specialists is well shown by the author in his preface when he says: "During the past few years the boundary lines of the territory which was formerly supposed to belong to the aural surgeon have been very materially extended. At first the larger part of the domain of rhinology was annexed, the legitimate right of such a transfer being recognized by all candid minds. Then later when it was discovered that many of the intracranial diseases of otitic origin previously looked upon as almost necessarily fatal were to a large extent curable, aural surgeons were obliged to decide promptly whether they should leave this new work entirely to the general surgeon or should assume all its grave responsibility themselves. The great majority of them accepted the trust without any hesitation, and the numerous reports of successful operations that have been published by them in recent years both abroad and in this country show that this new domain has been rightly added to the aural surgeon's former territory.

The author, who is an experienced editor as well as an able practitioner, has here accumulated an enormous mass of facts and has set them forth very skilfully; in consequence we have a text-book at once authoritative and attractive.

Manual of Chemistry. A Guide to Lectures and Laboratory Work for Beginners in Chemistry. A Text-book specially adapted for Students of Pharmacy and Medicine. By W. SIMON, Ph. D., M.D., Professor of Chemistry and Toxicology, College of Physicians and Surgeons, Baltimore; Professor of Chemistry in the Maryland College of Pharmacy. New (Sixth) edition. In one 8vo volume of 552 pages, with 46 engravings and 8 colored plates illustrating 64 of the most important chemic tests. Philadelphia and New York: Lea Brothers & Co. Price, Cloth, \$3.00 net.

We had the pleasure of reviewing the fifth edition of this work in 1896, and during the three years that have elapsed many important results of scientific progress have been recorded in this volume.

The peculiar feature of the book is the plates giving the actual color and color-changes of most of the important tests in science and physiology as a permanent set and standard of comparison for the determination of important questions depending upon the test-tube.

The author has not yet adopted fully the orthography recommended by the American Association for the Advancement of Science, but the decimal system has been strictly adhered to in all weights and measures, and degrees of temperature expressed in the same system, though the corresponding degrees of the Fahrenheit scale have been mentioned.

This edition is destined to retain the favorable opinion expressed of previous ones; and it well merits its deserved popularity.

King's American Dispensary. By HARVEY W. FELTER, M.D., and JOHN URI LLOYD, PH. M. New edition. Entirely rewritten and enlarged. Two volumes royal octavo, each volume containing over 950 pp. with complete indexes. Cincinnati: The Ohio Valley Co. Volume i. Cloth \$4.50 per volume, post-paid. Sheep \$5.00 per volume, post-paid.

It is a pity that such an excellent and so well known a book should have been printed on such thin paper as to cheapen its appearance.

The long period of time during which the work has been be-

fore the public has established its reputation as an exhaustive, learned and valuable contribution to medical literature. The present edition is lacking in none of the characteristics which have made previous editions so popular.

An Introduction to Pathology and Morbid Anatomy. By T. HENRY GREEN, M.D., F.R.C. P. Revised and enlarged by H. MONTAGUE MURRAY, M.D., F. R. C. P. New 8th American edition, thoroughly revised from the 8th English edition, by WALTER MARTIN, P.H.B., M.D. Illustrated with 216 engravings of which six are in colors. Pp. 582. Philadelphia and New York: Lea Bros. & Co., 1898.

The present edition of this book has been prepared from the eighth English edition. Many new illustrations have been substituted for less satisfactory ones in the last edition. The arrangement of the text has been altered and several new sections have been inserted. The new illustrations have been taken entirely from German sources.

A new section on some of the animal parasites has been inserted. In the section on tumors, glioma has been classed under benign new growths. Lymphomata have been omitted and placed under diseases of the lymphatic glands, and the class, endothelioma, has been introduced.

This popular text-book, by the frequent revision it has undergone, is kept fully up-to-date, and notwithstanding the rapid changes and great advancement made in pathology it will still be found fully abreast of the times.

The Medical Register and Directory of the Indian Empire. By JAMES R. WALLACE, M.D., F.R.C.S.P., Editor *Indian Medical Record*. Second edition, 1898. Cloth. Pp. 777. Calcutta, India: Barker Bros., 150 Dharamtala Street. 1898.

This volume's contents is arranged in seven parts. Part I containing: postal information; monies, measures, weights, etc.; calculating tables, ready reckoner; and medical items. Part II comprises initial nomenclature, the General Medical Council of Great Britain and titular distinguished members of the profession. In Part III the medical acts of Great Britain, medical education in the British Isles and in the Indian Empire occupy 338 pages, while Part IV has to do with the Indian Medical Association: The military medical services of India occupy 76 pages, i.e., Part V, while Part VI contains the retired list and Part VII a general alphabetic list of government officers, medical practitioners, etc.

Practical Diagnosis. The Use of Symptoms in the Diagnosis of Disease. By HOBART AMORY HARE, M.D., Professor of Therapeutics and Materia Medica in the Jefferson Medical College of Philadelphia. Third edition, enlarged and thoroughly revised. In one octavo volume of 615 pages, with 204 engravings and 13 full-page colored plates. Philadelphia and New York: Lea Brothers & Co. Cloth, \$4.75 net.

Three editions of this book have been called for in two years, which is sufficient indication of the popularity it has obtained in this country and Great Britain. The text of this third edition has been carefully revised, also important new matter has been added, and new illustrations, taken from life, by photography, have been introduced to render the text more practically useful.

This edition is intended as a companion volume to the seventh edition of the author's "Practical Therapeutics," which is published simultaneously.

The second edition of this book was only published last year, notwithstanding which fact it has been thoroughly revised, and the present edition will be found fully up-to-date, and the peculiar features which made the popularity of the former editions have been retained.

Notes on Disinfectants and Disinfection. By A. G. YOUNG, M.D., Secretary of the State Board of Health of Maine. Paper, 218 pp. Augusta: Kennebec Journal Print, 1898.

This volume is a reprint from the tenth report of the board and contains much of value to the physician. The author has endeavored to present a review of the experimental work which has been done, more particularly in recent years, for the pur-

pose of determining the germicidal value of the various agents which have been in use, or have been suggested as disinfectants. He gives some attention to their antiseptic and deodorant properties; also to the methods and conditions under which the investigations were made. The various subjects are considered in their alphabetic order and a decided value is given to the references to the literature, in that the date of the publication is included with the volume and page reference, showing at once whether the work is or is not recent.

The Student's Histology. A Course of Normal Histology for the Students and Practitioners of Medicine. By MAURICE N. MILLER, M.D. Revised by Herbert N. Williams, M.D. Third Edition, revised. Profusely illustrated. Pp. 259. New York: William Wood and Company. 1898.

This book is divided into three parts, the first consisting wholly of the technology, the laboratory, microscope and preparation of tissues for microscopic purposes. The second part is given up to the study of the structural elements of the body—connective tissue, cartilage, bone, muscular tissue, blood. The third part relates to the organs of the body, which include the skin, the circulatory system, the lymphatic system, the spleen, the respiratory organs, teeth, glands, alimentary canal, liver, kidney, male and female generative organs, suprarenal body, nervous system, spinal cord and the brain.

The work is well printed, the illustrations are fine and we commend the book.

Text-Book of Medical and Pharmaceutical Chemistry. By ELIAS H. BARTLEY, B.S., M.D., Ph. G. Fifth edition, revised and enlarged. Pp., 788. With 86 illustrations. Philadelphia: P. Blakiston's Sons & Co. 1898.

This edition of this popular book has been thoroughly revised, the chapter on nutrition, clinical examination of milk, gastric contents, vomit and feces having been largely rewritten. The size of the book has not been increased. The reformed spelling of chemic terms has been accepted in part. The work is full and complete, and deserves a place in the library of the progressive physician. For the student there is no more solid and trustworthy guide.

Official Messages to Board of Cook County Commissioners, 1894-1898, with an introduction, 1886-1894. By D. D. HEALY, pp. 207. Chicago: J. M. W. Jones, Stationery and Printing Company, 1898.

This book is of great interest to all interested in the hospitals and charities of Cook County, and whatever may be said in criticism of the fact that the largest hospital in the State is without a medical superintendent in charge, it must be admitted that the Board of Commissioners have gone before the public in the person of their most brilliant and skillful president.

The reforms which have been instituted, so far as they have gone, were necessary and in the interest of the people and of good government.

President Healy, in retiring from office, will have the satisfaction of having conscientiously and ably performed the onerous duties of his office with fidelity, courage and ability, and we believe all will concede in general terms the recommendations of President Healy that Chicago shall be placed under one system, and that within the city limits all county and township governments be abolished.

Proceedings of the Kansas State Medical Society. Paper. Pp. 124. Topeka: A. D. Bauer. 1898.

These proceedings are for the thirty second annual meeting, held at Topeka, Kan., May 5 and 6, 1898. The volume contains a list of the incorporators of the society, officers for 1897 and for 1898, a list of the ex-presidents, of the members, and the following papers: "Mule's Operation—a Substitute for Enucleation;" "Faith Healing and its Congeners;" "Rational Treatment of Ovarian and Uterine Diseases;" "Neurasthenia;" "Club Foot or Talipes;" "Some Laboratory Notes;" "Treatment of Cancer of the Cervix Uteri by Carbide of Calcium;" "Multiple Neuritis;" "The Malarial Parasite."

Archives of the Roentgen Ray. London: The Rebman Publishing Company. W. B. Saunders, Philadelphia, American agent. 1898.

The August number is now on our table and is a very entertaining one, containing extracts from the proceedings of the Roentgen Society, many original articles, besides the usual number of skiagraph plates.

A Laboratory Guide in Urinalysis and Toxicology. By R. A. WITTHAUS, A.M., M.D. Pp. 112. Fourth edition. New York: William Wood and Company. Price \$1.00.

This work, as its name implies, is a thorough guide to the laboratory, and is arranged so conveniently and the directions given are so minute that the student will find it well-nigh indispensable.

NECROLOGY.

FRANCIS L. HAYNES, M.D., Los Angeles, Cal., died October 18. He was born in 1850, in Pennsylvania, and at the age of 20 years received the degree of Doctor of Medicine and Bachelor of Philosophy, from the University of Pennsylvania. Immediately upon his graduation he became interested in the Philadelphia Episcopal Hospital, where he remained for eighteen months, and was afterward connected with this institution as visiting physician. He practiced continuously in Philadelphia until May, 1887, when he removed to Los Angeles on account of ill health, and was elected professor of gynecology in the Medical University of Southern California. In surgery, he was the apostle of antiseptics in Southern California. He was also interested in sociology and allied subjects, and was appointed by Governor Markham trustee of the Whittier State School, being an active member of that board when the Whittier school was at its best. For the past eighteen months, Dr. Haynes has been obliged to abandon his work, and for a long period before that he could work only intermittently.

MARIAN DECAUSEY, M.D., Sealy, Texas, October 21 aged 56 years.—Claude Everett, M.D., Promise City, Iowa, October 20, aged 27 years.—W. C. Forester, M.D., Birmingham, Ala., October 22, aged 37 years.—Louis C. Horn, M.D., Baltimore, Md., October 23, aged 58 years.—Julius A. Johnston, M.D., Alexandria, La., October 19, aged 45 years.—E. C. Miller, M.D., an instructor in the anatomic department of Northwestern University Medical School, Chicago, October 23.—I. J. Miller, Jr., M.D., Cincinnati, Ohio, October 23, aged 30 years.—Charles J. Milliken, M.D., Cherry Field, Me., October 16, aged 55 years.—J. H. Omo, M.D., Maysville, Ind., October 22, aged 65 years.—William T. Plant, M.D., Syracuse, N. Y., October 27, aged 62 years.—H. T. Snyder, M.D., North Wales, Pa., October 22, aged 33 years.—Hezekiah Starr, M.D., Baltimore, Md., October 23, aged 82 years.—Robert Stein, M.D., Dayton, Ohio, October 20, aged 37 years.—William N. Stowe, M.D., Wellfleet, Mass., October 17, aged 53 years.

SOCIETY NEWS.

An International Congress of Pharmacy will be held at Paris in 1900. Professor Planchon is the chairman of the committee of organization.

Society of Washington Ophthalmologists and Otolologists.—The first fall meeting of the Society, October 21, was called to order by the president, Dr. Swan M. Burnette. Dr. Newell read a paper on "Esophoria and Ciliary Spasm," and Dr. Belt one on "Inflammation of the Middle Ear."

Washington Gynecological and Obstetrical Society.—The 286th meeting was held on October 21, the election of officers resulting as follows: T. C. Smith, president; J. W. Bovee and Wm. P. Carr, vice-presidents; John Van Rensselaer, treasurer; J.

T. Kelly, recording secretary; Edwin F. Morse, corresponding secretary. The following committees were selected: J. T. Winter, F. L. Tompkins, F. E. Morse, business; W. N. Sprigg, H. B. Deale, M. F. Cuthbert, admissions; C. W. Cooke, H. B. Deale, J. T. Kelly, publication; G. N. Acker, W. C. Bowen and J. T. Kelly, microscopic. The Society adjourned to the annual banquet, held at the Arlington. In the course of the evening remarks were made by the following members: T. C. Smith, toastmaster; Drs. Prentiss, Magruder, King, Bowen, Bromwell, Fry, Bovee, Kelly, Stone, Van Rensselaer, Sprigg, J. T. Johnson, H. L. E. Johnson, Deale, Cooke, Adams, Cuthbert, Winter, Morse, Balloch and Acker. The latter was chairman of the banquet committee, and at the close the Society complimented him on the success of the evening.

Washington Medical Society.—At the meeting on October 26, it was resolved that the meeting on the 2nd prox. should be a memorial meeting, in honor of Dr. N. S. Lincoln, deceased. Dr. Stone presented the specimen and gave the history of a successful "Nephrectomy for Cystic and Fatty Degeneration of the Kidney." The patient was a woman, age 42 years, whom he treated at the Columbia Hospital. An interesting feature of the case mentioned was, that the patient gave no special symptoms of the disease, and was sent to the institution for supposed fibroma of the uterus. An incision was made over the mass, and the growth, containing several pints of fluid, was enucleated. Hemorrhage was severe, followed by shock, and required the intravenous injection of normal salt solution. The patient is now convalescing; two large calculi were found in the growth. The specimen was referred to the microscopic committee for special report. Dr. C. H. Allen read a paper on "Syringomyelia," and presented the gross and microscopic specimens. He gave a very interesting account of the history of the case, and went into the general subject of etiology, pathology and symptomatology of the disease. Dr. Robert Reyburn gave his personal investigation of the pollution of the Potomac water at Piedmont and Cumberland, Md., mentioning the cause and character of pollution, and giving an interesting account of the legal action of the residents of those cities in their endeavor to correct the abuses. He indicated the consequent danger to the water-supply of Washington City.

MISCELLANY.

Personal.—Dr. Robert Heesler, pathologist to the Central Indiana Hospital for Insane, at Indianapolis, has resigned, and will spend the coming year in study in Europe.

Reorganization of the Medical Department of the Navy.—It is understood that a bill to give a better standing to certain medical officers of the navy will be introduced at the coming session of Congress. It is certain that this corps deserves all the support and kindly recognition that a grateful country can give. The following is the text of the proposed bill:

AN ACT.—Be it enacted by the Senate and House of Representatives of the United States in Congress assembled:

That assistant-surgeons of the United States Navy, shall, from the date of their entrance into the service, rank with lieutenants (junior grade) of the line.

After five years from date of appointment as assistant-surgeons they shall be examined by a board of medical officers (now existing) and upon the successful completion of such examination, they are to be promoted to the grade of passed assistant-surgeon with the rank of lieutenants (senior grade) of the line.

That the higher grades are to take the rank of lieutenant-commander, commander, captain, and commodore respectively.

That all benefits derived from existing laws relative to the pay of medical officers is to continue the same, except in the case of assistant and passed assistant-surgeons ranking with lieutenants (junior or senior grade) provided for in this bill, whose pay is to correspond with lieutenants (junior or senior grade) of the line.

Argument.—Medical men enter the army between the ages of 21 and 28 years and take the rank of first lieutenant of cavalry, which corresponds to a junior lieutenant of the navy.

Five years from date of entrance into the army, they are by law promoted to the rank of captain of cavalry, which corresponds to a senior lieutenant of the navy. After this grade they are promoted to surgeon with the rank of major, which is equivalent to lieutenant-commander of the navy.

Diabetes Mellitus.—This is a rare affection in children, but three new cases have been recently reported—Haushaler, a girl of 10 years, and Seiffert (*Jahrbuch f. Kind.*). The pancreas was found typically atrophied in the two cases that came to the necropsy, weighing twelve and twenty-five grams.

Pathogenesis of Epilepsy.—Prof. J. Prus of Lemberg announces, as the result of extensive research and experimentation on dogs, that Unverricht's "irradiation theory" of the transmission of cortical epilepsy along the surface of the cortex is untenable, also that the pyramidal tracts do not participate at all in the transmission of cortical epilepsy. The excitation is transmitted from the cortex to the medulla oblongata in cortical epilepsy by motor tracts which he calls extra-pyramidal tracts, and which pass from the cortex to the medulla and the spinal cord through the upper part of the central brain, and cross in the medulla oblongata. These tracts not only transmit the reflexes but also the voluntary stimulus for complicated movements. He asserts that after anesthetizing the cortex with cocaine, no stimulus, no matter how powerful, would produce an epileptic attack; hence the stimulation of sensory nerves and cells is necessary to the production of an epileptic attack. He explains the epileptic attack produced by irritation of the cortex as the expression of the dynamic activity of the nerve-centers, or in other words, as a complicated reflex process produced by irritation of the sensory nerve elements of the cortex. The attack is generalized by means of the gray matter—middle brain, medulla and spinal cord. There are no special centers which are exclusively the seat of epilepsy, nor any essential differences between cortical and genuine epilepsy.—*Vienna Klin. Woch.*, September 22.

Communicability of Malarial Fevers.—Dr. Coronado of Havana has given (*Revista de Anatom. Patolog. y Clinicas*) views apparently contradictory to those of Koch, on the point of the contagious properties of the paludal fevers. If his observations are confirmed it will need to be taken into account that there exists at least a moderate or occasional element of connection by contact and fomites. In the first place, he has been able repeatedly to locate the plasmodium of Laveran in the excreta and vomit of fever patients; and this has been done in cases where there existed no hemorrhagic conditions of either stomach or bowels. He, with others, has found that the malarial parasite can exist in waters containing decomposing vegetal matters, as well as in sea-water; in well-diluted and sterilized broths the plasmodia live, grow and develop. He has noted also the coincident development of an aspergillus of a bright amber hue when the implantation is made in non-sterilized media. This is in concordance with the observation of other investigators with regard to the specific germs of other infectious diseases. The writer cites various clinical facts in support of this statement. Among the passengers on a small coast vessel running to Havana there were always some affected with malarial fevers. Shortly afterward the robust sailors, who had never suffered from malaria, were stricken with the disease. In all these cases repeated examinations of the blood revealed the presence of the plasmodium. He believes that the transportation of numerous malaria-stricken persons served to convert these vessels into real foci, and this can only be realized in the presence of contagious disease. If the known germ of paludism became exhausted in the disease organism, as has been supposed, the facts cited above would have no rational explanation. But these facts go to confirm what the writer

had already proven experimentally; that the dejections of persons suffering from malaria contain live germs whose existence may be easily demonstrated. Near a place called Candelaria there is a sugar plantation where four families have lived for over twenty years without ever having suffered from paludal fevers. As a result of the reconcentration into the town of Candelaria many malarial persons of the surrounding towns and villages took refuge there. Soon afterward various members of the four families referred to in the preceding paragraph began to suffer from various types of malarial fevers whose diagnosis was confirmed in the laboratory. Now, the mode of living of these persons did not vary in the least from other times, the water which they made use of was the same. It was only necessary for some reconcentrados to come in contact with these persons to provoke paludism.—*Ohio Sanitary Bulletin*, September.

Phototherapeutics of Measles.—Chatinière describes four cases of measles commencing with sudden and violent symptoms, which he cured by simply having the windows hung with red curtains, shutting out the white rays entirely and using a photographic red lantern at night. The disease completed its evolution in twenty-four hours to four days, every symptom vanishing, and the children were up, bathed and out of doors by the sixth day. One child complained that the light was too dim for him to play, and the parents took down the curtains, followed by an immediate return of all the symptoms, reappearance of the eruption and fever, with general lassitude, all passing away in two hours after replacing the curtains.—*Presse Méd.*, September 10.

Artificial Albumin.—Professor Lilienfeld recently read a paper before the International Congress for Applied Chemistry, at Vienna, on the artificial production of albumin. The *Scientific American* for September 10 says he found it possible to prepare pepton hydrochlorid by the condensation of phenol and glyccoll with phosphoric oxychlorid. The substance thus obtained gives all the reactions of albuminoids. By previous conversion into the sulphate and decomposition of the latter, free pepton was obtained which resembled, both in its chemie and physiologic behavior, the natural pepton from albumin. The analytic data corresponded with those given by natural pepton. Dr. Lilienfeld does not claim to have made albumin by synthesis, but to have made pepton—a digestion product of albumin. Chemists will not readily believe that pepton has been really synthesized, as a proteid molecule is so complex, mobile, and of such high instability, that a change in its constitution may be readily brought about, so that until more definite tests are made, and until Dr. Lilienfeld pleases to give more of the details of his processes, which he holds secret at present, pending the issuance of a patent, they will be apt to suspend judgment. Even if artificial albumin may be produced at a moderate price, it does not necessarily follow that it will in any way tend to solve the problem of food supply, and we are not sure as yet that the new product is physiologically identical with that produced in nature's laboratory. Pure albumin has been made on a large scale and it is not at all dear, but we are not aware it has ever occupied an important position in dietetics, or that it has been proposed as a substitute for ordinary articles of food; so that it is really absurd to think the time will come when we shall carry about a complete meal in a pill-box, and, like the artificial diamond, Professor Lilienfeld's discovery may not be valuable from a commercial point of view, certainly not while glyccoll is selling for some \$75 a kilogram. The subject of chemie synthesis is an important one, and in Germany alone, in scores of laboratories, chemists are actively experimenting along this line.

Artificial Immunity to Mixed Infection.—Bernheim reports from the Vienna Hyg. Institute that he has succeeded in immunizing goats with the streptococcus and diphtheria bacterium,

until their serum confers passive immunity against this mixed infection.—*Munich Med. Woch.*, October 4.

Fish Bones in the Alimentary Canal.—Three cases have been observed recently, in Copenhagen, of a chronic intestinal affection caused by accumulations of fish bones in the intestines. The fact that a fish diet does not oftener lead to this result was explained by Faber's investigations. He found that normally active gastric juice poured over fish bones dissolves the small bones entirely and partially digests the large ones, rendering them soft and transparent. After entering the intestines they pass through unaffected by the intestinal secretions. The patients in the three cases of obstruction noted were all below average intelligence and the gastric juice was also below the normal acidity.—*Hospitaltidende*, May 25.

Operations for Extra-Uterine Pregnancy.—Seventy-nine operations are reported by M. Strauch (*Wratsch*, 18), with no deaths. Laparotomy was performed 63 times. The hematocele was opened through the vagina 9 times; twice the uninjured, two-months' pregnant tube was extirpated per vaginam, and once the entire uterus was removed to arrest excessive hemorrhage. The youngest patient was 21, the oldest 46 years old. The ovus was found uninjured in nine cases. The right tube was involved in 31 cases, the left in 39; 16 were nullipara; 9 had borne a child a year and 16 over ten years before.

Obstruction of the Murphy Button.—Tieber reports a fatal case of obstruction of the lumen of the Murphy button by a plum-stone, and comments on several other cases in which the button became corked with hard fecal lumps, concluding that the use of the button should always be preceded by rinsing out the stomach and evacuating the intestines to remove foreign bodies, while liquid food should be given for a while afterward.—*Vienna Klin. Woch.*, October 6.

An Improved Canula.—A canula for irrigating the anterior urethra, designed by Professor Mendoza of Madrid, who indorses it warmly, consists of two concentric tubes, the inner projecting 1.5 mm. beyond the outer, which has slits in its sides to allow the immediate reflux of the fluid. The irrigation is completely restricted to the anterior portion alone, and the patient can accomplish it conveniently without assistance.—*Derm. Ztschft.*, September.

Results of Treatment of Glaucoma.—Seventy-six patients in Haab's private practice have been followed, and the results of treatment shown more satisfactorily than usually supposed. In acute inflammatory and chronic glaucoma 62.5 and 60 per cent. have been permanently cured, that is there is absence of all hypertonicity, and in the 8 cases of recurrence, the trouble was dissipated with myotics and only 2 proved incurable. In 91.5 per cent. the visual acuity has been preserved as good as before the iridectomy and, in some, it has improved. There has been no hypertonicity in 77 per cent. of the cases treated by iridectomy and in 60 per cent. with sclerotomy; the latter should be considered the secondary operation, and combined with myotics if necessary. The prognosis is much less favorable in hemorrhagic glaucoma; only 20 per cent. were cured and in 40 per cent. the vision retained. The less serious the intervention in these cases the better results, consequently sclerotomy is preferable. Haab has observed a slight hypertonicity at night, disappearing during the day, which may explain the cases in which the excavation of the optic nerve continues progressively, without evidence of hypertonicity.—*Presse Méd.*, September 24.

Penetrating Power of Formaldehyde.—This has been found to be greater than usually supposed, by Professor de Rechter of Brussels, who has been testing it in an apparatus with two connecting chambers in which human and animal cadavers were exposed to the fumes of 40 per cent. formaldehyde. The cadavers could be kept thus for a number of months without

showing any trace of decomposition, or it was arrested if it had already commenced. When the cadavers had been exposed a sufficient length of time, they could be kept a long while, without evidences of putrefaction, in the ordinary air. In cadavers of guinea-pigs that had died from anthrax or tuberculosis, and also in the lungs from tuberculous cows, the organs were found completely sterile in two to six days. The tests prove that the formol fumes penetrate the entire substance of the cadavers and positively kill the bacteria and anthrax spores in them.—*Munich Med. Woch.*, October 4.

Precautions in Artificial Respiration.—According to the Vienna correspondent of the London *Lancet*, August 27, Dr. Brosch, in an article published in the *Archiv. für Klinische Medizin*, gives an account of thirty-one experiments he has made in order to prove the possibility of the gastric contents being drawn into the lungs during artificial respiration. The greatest quantity of fluid which can be aspirated by artificial respiration amounts to 1210 c.c. The difference between experiments on the dead body and the conditions met with in the living subject is that aspiration of the gastric contents during artificial respiration is more easy in the living subject than in the dead body. The methods of artificial diaphragmatic respiration are the sources of the greatest danger. An experiment made by Dr. Brosch proved that even in the living subject, when the stomach is full, its contents may be pressed into the pharyngeal cavity by massage and that the cardiac orifice offers but a trifling resistance. An elastic tube introduced into the esophagus will prevent the contents of the stomach from finding their way into the air passages, and Dr. Brosch recommends that this precaution should be taken before artificial respiration is commenced.

An Important Gathering.—The Fifth International Congress of Hydrology, Climatology and Geology, opened at Liège in September with 240 attendants, almost all from abroad. Excursions to Ostend, Spa and Aix proved interesting illustrations of the addresses on mineral waters. The necessity of a department of public health in every country was emphasized. Felix of Brussels contended that this department should include in its scope, hygiene, labor and public assistance, as the only way to prevent and combat victoriously the causes of poverty and of physical and moral disease, to utilize economically and impartially the resources of benevolence by centralizing them, and to guarantee the laboring classes against the accidents and infirmities of labor and old age. He claimed in addition that the government should suppress distilleries altogether, stating that the revenues from alcohol had increased from 42,000,000 to 61,000,000 francs in 1896-97, showing the constant spread of the evil. He made an urgent appeal for sanatoria for convalescents, observing that the State should look after its wounded in the alcoholic slaughter constantly going on, and not be content merely to bury the dead. Ameyé described his process for sterilizing mineral waters without detracting from their medicinal value or altering the taste. They are slowly pasteurized in the bottles to 98 degrees C. and then slowly cooled. A special needle allows the escape of the impure carbonic gas and prevents breaking the bottles. The air is afterward extracted and the bottle filled with pure carbonic gas, which asphyxiates the organisms in the water deprived of air. The next Congress will meet at Grenoble in 1901.

Not Bound to Furnish Medical Attendance.—The supreme judicial court of Massachusetts holds, in the case of Davis vs. Forbes, July 14, 1898, which was an action brought to recover for personal injuries sustained by an employee, that the defendant was under no legal obligation to furnish the plaintiff with medical attendance, even if he had been liable for the injury. The case of a seaman injured on shipboard, it says, is different.

Verdict for Injuries to Nervous System.—Where, in an action to recover damages for personal injuries resulting from the negli-

gence of the defendant, the evidence tended to prove permanent injuries to the nervous system of the plaintiff, and especially to the nerves of her face, causing severe and protracted attacks of neuralgia and headaches, the court of appeals of Kansas holds, in *Atchison, Topeka & Santa Fe Railroad Company vs. Lee*, Aug. 10, 1898, that the allowance of \$1,000 for permanent injuries was not so excessive as to indicate passion and prejudice on the part of the jury against the defendant.

Preparation of Hypothetic Questions.—The first appellate division of the supreme court of New York says in *Preston vs. the Ocean Steamship Company of Savannah*, Aug. 10, 1898, that it seems to it proper that attention should be called to the constant abuse in the preparation of hypothetic questions asked medical experts to prove the prior physical condition of a plaintiff. It is often most difficult for the court to determine, at the time such a question is asked, whether there is evidence to sustain a finding that all the facts that the witness is asked to assume did exist; and counsel should always remember that, continues the court, if a hypothetic question of this character is allowed, and if anything is assumed not based upon facts either admitted or established by evidence, or which, if controverted, the jury might legitimately find on weighing the evidence, an exception to the admission of such a question may be fatal to a verdict.

Can Not Test by Habeas Corpus.—In the case of *People ex rel. Birkholz vs. Jonas*, where the relator had been committed to the county jail by a justice of the peace of Cook County, in default of payment of a fine imposed for the practising of medicine without a license, the supreme court of Illinois holds that he could not by habeas corpus proceedings test the constitutionality of the act to regulate the practice of medicine under which he was convicted. It says that the justice of the peace had jurisdiction to hear the case and to render the judgment against the relator, which was complained of, and in doing so said justice had full power and jurisdiction to decide all the questions involved in the case, including the question whether or not the law under which the prosecution was instituted was constitutional. The fact that the court was an inferior one, and that its decision of a constitutional question might not be of great authority as a precedent, did not change the case in any degree. If he chose, the relator could have appealed from the judgment of the justice, and have had a trial *de novo* in a proper court of record, in which trial he could, by presenting propositions of law, have preserved for review the constitutionality of the law under which judgment was rendered. For these reasons, the writ of habeas corpus was denied.

Attending Physician Alone Prohibited.—The Pennsylvania act of June 18, 1895, is in the following words: "That no person authorized to practice physics or surgery shall be allowed, in any civil case, to disclose any information which he acquired in attending a patient in a professional capacity, and which was necessary to enable him to act in that capacity, which shall tend to blacken the character of the patient, without his consent." It will be seen at once, says the supreme court of Pennsylvania, in *Wells vs. the New England Mutual Life Insurance Company*, July 21, 1896, that the act establishes a personal incapacity only. It is the physician attending a patient who is prohibited from testifying to information acquired while rendering professional service. He is prohibited by the words, "no person authorized," etc., "shall be allowed to disclose any information," etc. No other person who, being present at the time when the information was communicated, heard the same, would be prevented by this act from testifying to the very matter in question. It is only the physician himself who is prohibited, and that is manifestly on account of the professional relation between himself and his patient. Where a physician was examined as a witness, and his deposition taken, at a time anterior to the passage of the

above act, and at that time he was perfectly competent to testify to the matter in question, but subsequently, and before the trial in court, died, and the act above quoted was passed, the court holds that it was error to rule out the deposition because of the incompetency of the witness at the time of the trial if he had been living.

May Testify as to Another's Bill.—A judgment obtained for the amount of a bill for medical services was reversed by the supreme court of South Carolina, in the case of *Ward vs. the Ohio River and Charleston Railway Company*, July 19, 1898, because of the refusal of the circuit judge to allow an expert witness, a physician, to testify whether the bill for medical services was unreasonable and too high, notwithstanding the witness had heard the plaintiff, as a physician, testify to said charges, and had also seen the foot that was treated. The judge ruled that, as an expert, the witness could not give his opinion on the facts of the case. But the supreme court says that it is unable to distinguish between lawyers and doctors as witnesses, for a lawyer is allowed to give his opinion in court as a witness touching the value of a brother lawyer's account for services. Why may not a physician testify in the same way as to the compensation sought by a brother physician? The jury are not concluded by the opinions of either lawyers or doctors. They may still weigh the evidence (the opinions of experts) by reference to the nature of the services rendered, the time occupied in their performance and other attending circumstances, and by applying to them their own experience and knowledge of the character of such services. The court adds, these observations are directed to those cases where there is the absence of an express contract between the parties as to such charges.

N. Y. School of Clinical Medicine.—The forthcoming "Prospectus" of this school will contain, among other additions, the names of Prof. Herman Collyer in gynecology, Prof. John J. Morrissey in practice of medicine, and Associate Prof. M. Kenyon, operative surgery on the eye and ear. Louis Fischer, M.D., has been elected secretary.

Washington.

HEALTH OF THE DISTRICT.—The report of the health officer for the week ended October 22 shows the total number of deaths to have been 119, of which 62 were white and 57 colored. At the close of the week there were 134 cases of diphtheria and 105 cases of scarlet fever under treatment.

San Francisco.

NEW MEDICAL BUILDING.—October 22, the new home of the Medical Department of the University of the State of California was formally opened and dedicated. For eleven years this department of the university has been fighting to obtain from the State a more suitable building, and this event was the closing scene of the long struggle. Dr. Cole delivered the opening address, which was followed by one by Regent Dr. Rowell. His and the address of the president of the University, Prof. Kellogg, were very significant of future intentions regarding the Medical Department. It is the open and avowed desire of at least two members of the Board of Regents, to see the Medical Department take the leading place in medical education in this country. The address for the faculty of the Medical Department was by Washington Dodge, M.D. Miss Rachel Leona Ash, B.S., University of California, and a senior student of the Medical Department, then presented, in the name of the women graduates of this department, an oil painting of the late Adolph Sutro, the donor of the land on which the affiliated colleges are built. Dr. R. Beverley Cole, as the president of the Medical Department, accepted the gift of the portrait of Mr. Sutro, in the name of the faculty, and assured the donors that it would be placed to their satisfaction. After the close of the exercises the regents, faculty and invited guests were served lunch in one of the recitation rooms.

The regular college work in the new building commenced on the 24th.

Philadelphia.

DR. HUIDEKOPER RETURNS.—The hospital ship *Relief*, with 238 sick soldiers from Porto Rico has reached this city. On board was Dr. Rush Shippen Huidekoper, who has been detached from his command in Porto Rico to report before the investigating committee at Washington. In an interview with a press reporter he stated that he was still chief surgeon of the United States troops in Porto Rico, and would return to his duties there after reporting before the investigating committee in Washington.

ST. JOSEPH'S HOSPITAL.—The forty-ninth annual report of this hospital has recently been issued: Bequests of the late George S. Pepper, amounting to \$35,687.50 have been received, the interest only of which is available. During the year just closed a total of 1814 patients were treated in the hospital, 722 free of charge, while 30 paid a small amount, really less than the actual cost of maintenance, and 1062 made a fair compensation, the excess over net cost being devoted to the general expenses of the institution. The intimate relationship which the hospital bears to municipal needs is demonstrated by the fact that the service of the police patrol brought 459 cases of injuries and emergencies, while the ambulance service responded to 274 calls, the total number of accident cases treated in the receiving ward and house being 1515. The most notable improvement of the year is the building of a new wing at the Seventeenth Street entrance, in which has been installed a thoroughly equipped pathologic laboratory.

PEACE JUBILEE.—Although this city has been crowded by hundreds of thousands of visitors to see the Peace Jubilee parades, and although most of these people were upon about nine miles of streets, there have been but comparatively few casualties reported, and only one which has resulted fatally.

MORTALITY STATISTICS.—The total number of deaths for the week ending October 29, was 348, being a decrease of 41 over last week, and a decrease of 1 over the corresponding period of last year. Of the total number of deaths 87 were under five years of age.

LECTURE.—At a recent meeting of the Fellowship of Ethical Research, Dr. Daniel G. Brinton delivered an address on the "Diseases of Nations." He is quoted as treating the nation as an organism like the human body, and discussed such diseases as render it incapable of self-preservation. The speaker then stated "That according to history the average life of a nation was from 800 to 1000 years, its disintegration for the most part being due to moral diseases, as corrupt government, or priesthood, though nations do not fail from psychologic cause." The etiology of the diseases of nations he thought due to imperfect nutrition, poisons, mental coma, and sexual aberrations, each one of which received due consideration from the speaker; reviewing the causation factors in the health and welfare of this country, Dr. Brinton believes that our mode of life, use of stimulants and drugs might have some tendency toward mental coma.

ANOTHER HOSPITAL TRAIN.—The German Hospital recently sent another train to Camp Meade, returning with thirty-six soldiers, many of whom are suffering from typhoid fever. The train was in charge of Dr. Charles Turnbull of the hospital staff, the medical department being under the charge of Dr. Carl Frese. The Board of Trustees was represented by Horace E. Smith, and the Government by Major Peyton. It is stated that the entire expense of the train was borne by John D. Lankenau, President of the Board of Trustees of the Hospital. The Government also brought back twenty-two soldiers to be distributed to the different hospitals of the city.

RESULTS OF WIDAL REACTION.—Out of twenty-five cases of fever among soldiers recently admitted to the St. Joseph's Hospital, Dr. Joseph Sailer reported that in fifteen cases a positive reaction was obtained, and all subsequently turned out to be typhoid fever, while in several in which a negative

reaction was obtained they subsequently proved not to be typhoid. Dr. Pease of the Bureau of Health states that as a result of his examinations the positive reaction has been subsequently confirmed by a clinical history of typhoid in 97 per cent. of the cases.

SOLDIERS TO JEFFERSON HOSPITAL.—Jefferson Hospital was one of the first institutions here to offer its facilities for the treatment of sick soldiers of the Government. Not only this, but the whole graduating class volunteered their services in case of need. Appreciating the courtesy, the Government recently dispatched a hospital train carrying twenty-four men from Camp Meade to that institution.

CONTRIBUTIONS TO NATIONAL RELIEF COMMISSION.—Mr. George C. Thomas, through the banking firm of Drexel & Co., makes the following statement regarding contributions for the relief of sick soldiers: Cash previously acknowledged, \$77,294.35; value of supplies contributed to date, \$40,345.00; total, \$117,639.35. In addition, the "Medico Chi." reported contributions aggregating \$5,229.67, and the Woman's Hospital, \$339.20.

MUNICIPAL HOSPITAL.—One day this week fire broke out in the drying room of the laundry connected with the Municipal Hospital, in which are many patients suffering from diphtheria and scarlet fever. Some excitement was necessarily occasioned for the time being, but the flames were promptly controlled, and the damage sustained was small.

CHANGE OF ADDRESS.

Bellamy, R., from Newport, R. I. to 210 W. 57th Street, New York, N. Y.
 Brock, G. S., from Bush to London, Ky.
 Birdsall, W. G., from Denver, Colo. to El Paso, Texas.
 Collins, B. F., from Toronto to 215 N. Phelps Street, Youngstown, Ohio.
 Clements, G. E., from Crawfordsville, Ind. to 757 W. Monroe Street, Chicago, Ill.
 Campbell, W. H., from 330 W. Fourth Street to 330 E. Fourth Street, Cincinnati, Ohio.
 Druet, A. L., from Marysville to Anamosa, Iowa.
 Gessner, H. B., from 731 Carondelet Street to 1450 N. Rocheblane Street, New Orleans, La.
 Gibbs, M. D., from Macon to Gillett, Colo.
 Hoffman, A., from 174 Ashland Boul. to 6041 Vernon Ave., Chicago, Ill.
 Jones, C. C., from Brock to John Sealy Hospt., Galveston, Texas.
 Leach, W. D., from 1125 to 1087 Washington Boul., Chicago, Ill.
 McKiven, F. G., from 103 Byers Street to 150 So. Broadway, Denver, Colo.
 Monette, G. N., from 1124 St. Charles to 1021 Baronne Street, New Orleans, La.
 Reed, J. H., from Burnett's Creek to Hammond, Ind.
 Rietz, P. C., from Chicago, Ill. to Evansville, Ind.
 Shortridge, W. R., from Monroe, Wis. to Elgin, Ill.
 Ussery, W. C., from St. Louis, Mo. to Paris, Ky.
 Vedeler, C., from Locust, Iowa to 715 W. Harrison, Chicago, Ill.
 Van der Veen, C., from 143 Fountain Street to 554 Grandville Avenue, Grand Rapids, Mich.
 Wertz, J. A., from 509 Third to 861 Trumbull Ave., Detroit, Mich.

THE RELATIONS OF PELVIC AND NERVOUS DISEASES.

WITH SPECIAL REFERENCE TO OÖPHORECTOMY FOR FUNCTIONAL NERVOUS DISORDERS.

Presented to the Section on Neurology and Medical Jurisprudence, at the Forty-ninth Annual Meeting of the American Medical Association, held at Denver, Colo., June 7-10, 1898.

BY ROBERT T. EDES, M.D.

JAMAICA PLAIN (BOSTON), MASS.

The question before us is one of great importance, and has presented difficulties fully commensurate therewith, but experience, more accurate and trustworthy if less fascinating and brilliant than the most ingenious theorizing, has answered at least a part of it.

There can be no doubt as to the frequent and important relationship existing between the two sets of symptoms under discussion, but the nature of the connection and the way in which it is established in each individual case is a matter by no means so clear, while the interpretations which may be put upon the same set of phenomena differ as widely as the theories and prejudices of those who are called upon to make the decision. The ease with which all nervous symptoms may be so simply and confidently referred to disorders of the pelvic organs, and the equal facility with which objections on the ground of physiology or experience may be silenced by a jaunty and wholesale use of that much-misunderstood and overworked word "reflex," have settled it as a well-understood fact in the minds of a large part of the laity as well as of the profession, that if a woman is "nervous," and has at the same time some uterine displacement or inflammation or neuralgia, the real cause of her sufferings has been found, and there can be no doubt of the relation of cause and effect between them. The belief has led to a vast amount of gynecology and surgery useless and worse than useless.

I presume it is true that the popular ideas are often more extreme in this direction than those of the most conservative, at least, of the profession, and that a certain amount of treatment is undertaken quite as much to satisfy the wishes of the patient or her friends, as to carry out the requirements of a well-considered diagnosis. But the popular medical errors of today, as has been shrewdly remarked, are the professional medical errors of a former generation, and women believe as our predecessors taught their mothers, and not as we would teach themselves. In great numbers of the cases of chronic invalidism familiar to most of us, the mutual interaction of somatic and psychic influences has made so complicated an entanglement, that in the individual case the truth is by no means easy to trace; and when the practitioner has placed before him for immediate adoption one or the other of two extreme alternatives, that which brings into the

foreground distinct symptoms and definite lesions susceptible of operative interference, is naturally enough the more attractive. This apparent decisiveness and practicality, combined with a full appreciation of the safety of modern surgery, have led to an immense amount of activity that has done more harm than good.

There are two distinct ways in which the influence of the pelvic organs upon the nervous system is felt. In the first, the diseases of the uterus, ovaries and adnexa produce the same amount and kind of nervous symptoms that other wasting and painful diseases may do, either directly, or indirectly by way of anemia and impaired nutrition. It has often been remarked that hysteria is not usually found in connection with gross organic disease of the uterus, and the same is true of the more vague condition of neurasthenia. Even with such lesions as displacements, which might be supposed—as keeping up a more permanent irritation of a low grade—specially prone to cause functional disturbances; we find the latter associated, not so much with an extreme procidentia, for instance, as with those slighter forms only to be detected by the trained senses of the specialist. In other words, when well-marked and clearly diagnostic lesions of the pelvic viscera coexist with the well-marked nervous symptoms, there is no close correspondence in the severity of the two sets, and it seems to me more philosophic, without denying all influence to the pelvic viscera, to assume that in the great majority of cases the pelvic lesions are certainly not the only factor—and perhaps not even the important and causative one—but rather are coexistent and dependent either upon two different causes or upon a single one underlying both, which may often be a general impairment of nutrition. The fact that the attention of nervous patients is so frequently and strongly directed to the pelvic organs proves no more and no less than the kindred facts of "nervous dyspepsia," cardiac disease or "spine disease."

The second of these ways is that much less easily explicable influence which the physical development of the sexual organs, normal or abnormal, exerts upon the growth and functions of the nervous system in some of its higher manifestations—evident at a very early age, rising to its greatest activity during the period of complete sexual development, and again decreasing or disappearing after the time of involution. Here also it is quite as true that the two developments, pelvic and nervous, are coincident, rather than that either is strictly consequent upon the other. Certain it is that interference with the normal relations and development of the two under the influence of improper education, social conventionalities, or conflicting interests, has much to do with the production of certain forms of nervous disease.

Like many other well-known facts, these relations are open to wrong interpretation on both sides. They may be, in the individual case, obscure and totally overlooked and all connection denied, though of this

error in practice the risk is slight. If the practitioner be inclined to forget, there is usually a hypochondriac patient or her disinterested friend to remind him. On the other hand, their importance may be grossly exaggerated. While we have admitted the close connection and parallel growth of the sexual organs and portions of the nervous organization, it is probably true that after a time, perhaps an early one, the habit of growth on each side becomes fixed and can progress independently of the other, so that nervous peculiarities which at first were closely connected with the sexual development have become established, and remain with comparatively little reference thereto. It is understood that among animals the effect of castration upon the general growth decreases according to the degree of maturity already attained, and the same thing is undoubtedly true of the human being.

The cessation of sexual activity in the female is marked in the popular, even more than in the professional mind, by a decided tendency to nervous as well as physical disorders. The more gradual changes, or perhaps rather, fixation or crystallization, of mental characteristics, which go on slowly and gradually for some years in both sexes, being emphasized in the female by a well-marked and definite phenomenon, are very likely to be referred to that phenomenon as a cause, if, as not infrequently happens, those peculiarities approach the borders of mental unsoundness or exaggerated nervousness. In by far the greater number of cases the "change of life" is accomplished with but little disturbance, but it is exceedingly difficult to disprove to the patient that vague effect so commonly attributed to it, in view of the long time over which its influence is often suspected to be felt, sometimes hardly less than a fourth of the allotted years between the cradle and the grave. A woman is very apt to begin to think about it if she has any ill-defined nervous trouble at the age of 35 years, and will not cease to do so until it is accomplished, which may not be until she is 55.

Weir Mitchell has had the records of a large number of cases of melancholia examined with reference to the age at which they began, and finds no statistical ground for attributing its occurrence, as is so often done, to the change of life. In regard to neurasthenic symptoms it is certainly not strange that they should be more marked at a time when the general vigor is on the wane; when outward circumstances are very possibly of a character to throw one back upon her own resources, and call attention to her own physical and psychical peculiarities, but there is certainly no close limitation to the precise period marked by the cessation of the menstrual function. That crystallization of character which is likely to take place as years advance occurs in both sexes, and may be much earlier in one person than in another. Dr. Holmes' allusion to old women of both sexes is sufficiently familiar, as well as the complaint of Admiral Jervis that the Channel Fleet was commanded by "a lot of old women disguised as young men." If the connection were a very intimate and causative one we ought to see, instead of mental troubles coming on at the menopause, a very marked and positive cessation of them when the "change of life" is accomplished, which is very far from being the rule, although such exceptions do occur.

Looking at these relations from a therapeutic point of view, we may consider the treatment of nervous disorders by local treatment of the pelvic organs, and

on the other hand, the influence of agencies acting through the nervous system upon disease of the pelvic viscera. It seems to go without saying that if a local cause of irritation is keeping up functional nervous disorders, it should, if possible, be removed, unless the removal will leave behind more trouble than it will take away. This is the question to be decided as each individual case comes before us, and is to be answered in the light of experience rather than as a matter of abstract probability. It is to be answered from the combined knowledge of the gynecologist and neurologist, united perhaps in the person of the same physician, but never by the mere operator anxious for a "record." When diagnosis is clear and treatment certain, or as nearly so as can reasonably be expected, there is little more to be said, but when the advantages to be expected from local treatment are somewhat doubtful and when it means feeling one's way through a wilderness of doubtful diagnosis to a merely possible cure, then even minor gynecology becomes of questionable benefit, and the very decided offsets should be carefully weighed.

A mass of hypochondriacal delusions can be more easily built up on this basis than on any other unless it is on the "spine." To be sure heart and lungs and liver and blood may serve their turn, but are more easily ruled out on account of the greater definiteness of the symptoms which can reasonably be assigned to them. Tradition, popular prejudice and accident play no inconsiderable parts in giving "that bad eminence" to the pelvic organs. An attack of "uterus on the brain" is not always wholly the fault of the patient. Like many other psychic abnormalities and superstitions it may be the result of faulty education, for which the over-enthusiasm of our own profession is often largely responsible.

When, however, we come to that less explicable and definite but no less real relation, where the functional activity, normal or abnormal, of the pelvic viscera is closely allied with nervous and mental manifestations and where pelvic disorder, instead of being, like lesions in other organs, simply a source of irritation, wasting or infection, is the origin or, perhaps more correctly a part and parcel of the nervous disorder, then the question of surgical interference is less easy to answer. If we are to look upon the growth of the two systems in question as rather corresponding and harmonious than as consequential, it is certainly possible or probable that after the early stages either one of them may pursue its course independently, if the other be abruptly interfered with.

It is certainly conceivable, on the other hand, that in many severe neuroses the removal of the most essential organs of the sexual system might be of great benefit, and we must look to experience rather than to a priori considerations for a decision. Under the stimulus of this theory and of hope, combined with confidence in the present security of surgical manipulations, the experiment has now been made many times.

If it were possible to anticipate by years the fate of each child; if we could know as a certainty, as we can now guess, what might be the abnormal tendencies in each, and what would be its opportunities for the restraint and correction of them, it is far from improbable that such an operation might prevent or modify their further development—although at the price of checking other growth—and would be a great source of relief to the patient, the family or the community..

This is as likely to be true of the male sex as of the other. But who would take this responsibility? Certainly not the physician, who knows that his fears are not always justified, and is aware how much may be done by training and by medicine. Who would voluntarily submit to it? Certainly not those who need it most.

In our present conditions of diagnosis and of civilization, it is as impracticable as the imprisonment from infancy of the hereditary thief or the hanging of the murderer before he has selected his victim. But experience in men and animals goes to show that if this change is effected later in life, its action upon the general sexual characteristics is much less. The growth and development has been accomplished and remains comparatively unchanged. Unfortunately, it is this condition which most closely represents the results usually found when it is sought to relieve the chronic nervous sufferer by a so-called "normal" oöphorectomy. The nervous disposition remains the same after the psychic effects of the operation per se have passed off, with the additional burden of new locations and excuses for pain, and the disappointment of a last resource tried and failed.

It has happened to me to have brought to my attention a considerable number of cases, which, for one reason or another, connected for the most part with nervous conditions, have had ovaries removed, either healthy or not seriously diseased. It would be, of course, entirely unfair to conclude statistically from these that the operation is nearly always a failure, for it is only the failures which call for further treatment, while the successes do not present themselves at "nervines." I have, however, taken pains to inquire for other cases of which these patients may have heard, since they are not likely to take so important a step without some definite encouragement, but without getting hold of enough of them to make me change my opinion.

I have heard of the remark having been made by some distinguished obstetrician that every woman who has been able to get out of bed unharmed in less than a week after confinement, was a curse to her sex, and a similar view might properly be taken of the very few successful cases of "normal oöphorectomy." Four years ago I reported upon twenty cases of this kind which had come to my knowledge, which gave one case of complete and decisive recovery apparently due to the operation, one (aged 40) in fair health, the operation in this case having been done for actual ovarian disease; one death, after many years of invalidism, succeeding the operation, but in no way connected with it; one death from cocaine; one hopelessly insane. Some of the remainder, except one not heard from, were invalids for some years, and many are still so. In a few there was improvement as regards dysmenorrhea and local pain, without any material change in the general condition. I do not know what happened to most of them during the last four years. Fifteen others have come to my notice since, some of whom were inmates and some applicants for admission to an institution for the care of nervous cases. My information as to some of them is not sufficiently minute to make a statistical statement of much value. Two of them, some years after the operation, were "better," or "much better," but of the eight with whose cases I was more acquainted, only one seems to have experienced any benefit, and this of a doubtful character. She had

the ovaries removed in 1894; grew worse until 1896; had the uterus removed in 1897, and went home "well." She seems, by her letter, to have had considerable sickness since, but is now "gaining and hopeful," a not unusual frame of mind for a time, but not always confidentially shared by the physician who has the opportunity to watch such cases after the first enthusiasm has worn off. One died after a condition of extreme nervousness with hallucinations, but it is not probable that the operation, which was for actual ovarian disease, had anything to do in one way or another with the final symptoms. It can only be said that it had not cured her nervous condition. One shot herself six months after a "very successful operation."

Mrs. J., a corpulent, dark-complexioned woman, had a variety of severe hysterical symptoms, ostensibly as the result of a fall from a bicycle. After much ineffectual treatment, her ovaries were removed. I heard, from time to time, of the continuance and aggravation of her mental and nervous symptoms, and after some time she sought readmission to the institution where she had been treated previous to the operation.

Mrs. M., decidedly neurotic, was much grieved by the death of a daughter in early childhood. She was operated on for an appendicitis, in which one ovary was involved, with, according to her own statement, the distinct stipulation that the other was not to be meddled with. The surgeon, however, saying that there would probably be something the matter with it by and by, removed this also. Her disappointment and indignation at the breach of trust, and the loss of the possibility of another child was justifiably extreme. She is now a broken-down and incorrigible narcotist, saying that she has nothing to live for, and refusing to give up her morphin.

A young woman, of much courage and energy, but neurotic heredity and antecedents, had vertigo and some curious notions of the agoraphobic type, which she managed partially to conceal, knowing them to be morbid. She had both ovaries removed, and afterward managed to get through a training-school for nurses. She soon broke down again, and although, after long rest she improved somewhat, again went to pieces on slight provocation.

The others present no special points of interest.

Notwithstanding these unfavorable results and the conviction that on the whole these cases did no better than, perhaps not so well as, the same number submitted to a sufficiently prolonged and careful non-operative treatment, it would be going too far to say that the operation is never justifiable. There are cases whose nervous symptoms are so severe and so utterly rebellious to all other treatment that the slightest chance of getting rid of them, even at the risk of establishing new ones, may justifiably be taken. They can not be much worse, and they may be a little better.

Such cases are far from common, and can not be made to cover a tithe of the operations which have been done. The inconvenience and sufferings of dysmenorrhea, local pelvic neuralgias, and the more remote conditions of neurasthenia, dyspepsia, headache and others, are only in the rarest possible instances adequate excuse for it. The objection, however, arises not from the fact that there are undesirable accompaniments, for the price of comfort, even if not of cure, would not be too great to pay if one could be sure of obtaining for it the desired result, but because in the vast majority of cases the price is paid and can not be recovered, while the relief is either none at all or only such as may be temporarily obtained from any strong impression whose effect is hopefully awaited.

In nineteen-twentieths of the cases, normal oöphorectomy stands on the same basis as regards its immediate effect on the patient as any of the popular forms of faith cure. No form of functional trouble

of the nerves, even when supposed on good grounds to be connected with disease of the pelvic organs, should be submitted to oöphorectomy until every other means has been tried, not merely perfunctorily and as a mere excuse for operating, but methodically and faithfully.

On the other hand, what is to be expected of treatment of nervous symptoms as to its effect upon actual pelvic disease? According to the faith-curists of all sorts—everything; according to rational pathology, little cure but much relief in some cases. Every one knows how much the condition of nutrition influences the degree to which local symptoms become wearing and irritating upon the general system. Purely subjective pelvic sensations are not disease of the pelvic organs at all, and provided they are recognized as being what they really are, no one would pretend to treat them locally, but erroneous diagnosis has undoubtedly thrown many such cases, either into the hands of faith-curists, who have not failed to glorify themselves therefrom as cures of organic disease, or into those of operators, with the result already described.

On the other hand, we know how useless, and worse than useless, it is to persuade a patient with cancer or fibroid that her pain is only "nervousness," and hemorrhages of no consequence. The attempt to do so, if successful, may cost her life, and is little less than criminal. Faith-curists, whatever their sect, and whatever we may think of their claims or results in functional cases, are here the most rampant and dangerous of quacks.

From all which it follows that, in this region, as in many others where medicine and surgery come in close contact, the diagnosis is the crucial point, and it should be made before the operation. Experiment with good results hoped for is not justifiable, and "art for art's sake" is no motto for the surgeon.

THE METHODS EMPLOYED IN EXAMINING THE EYES FOR THE DETECTION OF HYSTERIA.

Presented to the Section on Neurology and Medical Jurisprudence, at the Forty-ninth Annual Meeting of the American Medical Association held at Denver, Colo., June 7-10, 1898.

BY CASEY A. WOOD, M.D.

CHICAGO.

Although much has been written regarding the value of the ocular signs and symptoms of hysteria in the diagnosis of that disease, I believe there is good reason for returning to several matters in this connection that seem to me of vital importance, especially as I do not think sufficient stress is commonly laid upon the means by which one must arrive at diagnostic conclusions.

My own belief, after a somewhat extended acquaintance with this disease is, that, if one were to make a special study of that organ that most uniformly exhibits the evidence of hysteria, the eye would afford the most information, even more emphatically than the skin or the mucous membranes. On the other hand, anomalies of the general sensibility are probably more easily detected by the average individual (who methodically searches for them) than are ocular defects. But as the scientific observer omits no examination that will assist him in arriving at proper conclusions in diagnosis, prognosis or therapy, I enter a plea for a more thorough and more general use of

certain methods employed by the ophthalmologist in detecting the presence of ocular hysteria as one manifest of the general neurosis.

First of all, then, what are the commonest ocular manifestations of hysteria, what the most reliable means for their detection, and how may errors in examination be avoided? I need hardly say that some acquaintance with the use of the ophthalmoscope is of great value in the diagnosis of ocular hysteria, and in investigating the subject one should be certain that there are no alterations in the interior of the eye to account for the visual disturbances. It is not fitting that I should point out the value of ophthalmoscopic examinations to the trained neurologist; I do not very well see how he can dispense with them. Should he be unable to examine the background of the eye with the mirror he should at all events, seek a report upon the condition of the fundus at the hands of some confrère expert in that work. As is the case with other organs of the body, there are absolutely no tissue alterations to be found in any part of the eye, due to the presence of hysteria. A negative report upon the fundus condition is, therefore, a *sine qua non* in examining a suspected hysterope.

ANOMALIES OF ACCOMMODATION.

Taking one age with another, the commonest ocular sign of hysteria is a defect in the focusing power of the eye—anomalies of accommodation. For various reasons these conditions have been called *hysteric insufficiency of accommodation*, *ciliary paresis or paralysis*, *painful accommodation*, *nervous asthenopia*, etc. The patient complains of the usual symptoms of asthenopia—pain in the eyes and forehead when attempting to read or do any other near work, blurring of print, photophobia, frequent winking, etc. These cases are rarely permanently relieved by glasses or by an exclusive local treatment of the eye. In all there is a defect in the range of accommodation. This so-called paresis of accommodation is nearly always in the form of a true hysteric contracture of the ciliary muscle—the motor power by which the eye is focused for various distances. The nearest point for which the eye can accommodate itself for the distinct seeing of small objects varies with the age of the individual. As you are well aware, this point is quite close to the eye in childhood, remote from it in old age. On the other hand, every eye has a certain range of accommodation; that is, there is a certain space within which small objects can be distinctly seen, and when the eye is normal, or when the refraction is rendered normal by distance glasses, this range is singularly and wonderfully constant in individuals of the same age, and I believe that the neurologist who is on the lookout for deviations from the normal accommodations will obtain assistance in diagnosis by bearing this fact in mind. For all practical purposes, however, one may ignore the extent of this accommodative range and confine one's attention to the nearest point of distinct vision, that is almost always affected in hysteria, that is to say, is usually too near or too far away from the eye of the hysterope. The following table indicates the proper distance, and it is a very easy thing to determine any deviation:

Age.	Nearest point of distinct vision.
10	7 cm.
15	8 "
20	10 "
25	11.7 "

Age.	Nearest point of distinct vision.
30	14 cm.
35	18 "
40	22 "
45	28.6 "
50	40.5 "

An eye that is under the influence of hysteria acts either as if it were under the influence of pilocarpin or atropin; the patient is able to read fine print either abnormally near or sees small objects most distinctly farther away than he should.

In practice, all that it is necessary to do is to have the distant vision, if abnormal, corrected by glasses and then ask the suspected individual to read the finest diamond print, held as near to the eye as possible. The patient, with his back to a good light, is asked to read a portion of a page of this print, at the normal distance from the eye, as shown by the table. If he continues to read it when brought a couple of centimeters or more nearer, or if he cannot read unless it is removed farther away than the normal distance, a defect of accommodation is certainly present. I recommend this as one of the most satisfactory and most easily applied of all the tests. As in other forms of spasm or paralysis of accommodation, the condition may often be relieved by glasses. It often happens that a young subject must be treated as if he were sixty years of age, requiring a strong convex glass for reading at the normal distance or a concave glass for street wear. In both instances a few drops of a 1 per cent. solution of atropia will disclose the true refraction, often unmasking the hysteric character of the defect.

DEFECTS IN THE FIELD OF VISION.

As every neurologist knows, defects in the field of vision constitute some of the commonest signs of disease of the ocular apparatus, and that they are of paramount importance, while a knowledge of their peculiarities is of great value in determining the presence of hysteria. For purposes of comparison, I show two perimeter charts: one of the normal field and the other furnished by a hysterope under my care. The predominant peculiarity of an hysteric anomaly of the visual field is, that while in every other disease (except hysteria) where peripheral limitations occur, the color field is affected *pari passu*, or in a greater proportion than the field for white. In non-hysteric diseases perception of color is often entirely lost, and yet fairly large areas susceptible to visual sensation from a white disc remain. In hysteric amblyopia the field for colors is of greater extent or is less affected proportionately than the field for white objects, just the reverse of that which obtains in other nervous affections. Even where the field for white is still the largest it can usually be shown (when there is any perimetric defect) that the visual field for red is larger than that for blue, and measurements for these colors should always be made in doubtful cases. One of the best examples of this reversal of the color field occurred in the case of a young lady, aged 17, in delicate health, who began to complain of her eyes. She then noticed that she could not see well in the distance or read ordinary print with the right eye. There were no fundus changes; patient was distinctly hysteric; had attacks of weeping without apparent cause, pharyngeal anesthesia, lump in her throat, etc. She had spasm of accommodation, was able to read only coarse print and that at from 6 to 10 cm. in front of the eye. She could not read fine print at any distance. I wish

you would especially notice that her field for red is larger than that for white.

It must be remembered, that even where the patient does not complain of visual disturbances quite marked defects of indirect vision may be present. If these do not proclaim themselves at once they may be developed by fatigue of the retina. The patient is asked to look steadily for a couple of minutes at a near object and then the field for red and green should be mapped out, followed by that for white, and vice versa. The amblyopia may be so marked that the field for white and colors is reduced to the vanishing point, a condition of affairs which it is not improper to regard as an anesthesia of the perceptive elements of the retina and in correspondence with the loss or perversion of sensation exhibited by the skin and mucous membranes in other phases of the disease. In such instances it rarely happens, even where the central vision is reduced to 1/10 or 1/20 of the normal, that it prevents the patient from walking about as if he had good vision. I have now under my care a child who can not read the coarsest print at any distance, whose distant vision is reduced to finger counting at four feet and whose color-field and the area for white measure about 5 degrees, and yet to all outward appearances she has good eyesight, that is, she does not stumble over small articles of furniture placed in her path and her parents have difficulty in believing that her vision is defective.

My principal reason for referring to these defects in the visual field, so well known to all of you, is to insist upon a certain form of examination. Hysteria is essentially a fatigue neurosis and in the use of a subjective test like the perimeter one may easily obtain evidence that is quite misleading. In other words, mapping out the limits of the field of vision in a hysterope requires more time and patience than is generally given to it. In my opinion, all uncomplicated cases of hysteric defect show a concentric contraction and a fairly uniform boundary of the visual field. In the case whose field I show you there were, when it was first measured, several apparently reentrant angles, but these disappeared when the patient was allowed to close her eyes and rest for an instant every thirty seconds during the examination. I do not think that hand perimeters, or objects simply held in front of the face, should be used in examining hysteric patients. A stationary perimeter, accurately adjusted should always be employed and the suspected hysterope should remove the chin from the rest and close the eyes frequently during the examination. Moreover, only one eye should be examined at a sitting and control tests must be repeatedly made. I have often had an opportunity to observe the necessity for taking these precautions, and am convinced that improper conclusions may readily be drawn from the usual method of examination.

MONOCULAR DIPLOPIA OR POLYPOPIA

is a curious hysteric phenomenon, probably the result of ciliary spasm. When care is taken not to suggest it to the patient, it may be developed in many hysteroopes. I say developed, because, like defects in the field of vision, the patient is usually unconscious of the double vision, as such. It commonly presents itself to him or her as part of the visual defect and the manner in which the examination is carried out is of great importance. A test should be made in both a lighted and darkened room. In the former, one eye being covered, a white match is held vertically three

or four inches in front of the uncovered eye. As it is slowly moved from its first position to a point three or four feet away, the patient is asked how many matches he sees. In most cases the match will present a double image when held quite near the face; the images approach each other and become confused as they are removed, to again separate more and more until the meter distance is reached. The match is again, from this point, gradually brought close to the eye, when the same phenomena, but in reverse order, will be manifest. The second eye is similarly examined and, finally, the room is darkened and a further (control) test is made with a small candle flame. Sometimes three or more images (polyopia) are observed and it is usually possible to exclude one or more of these by interposing a card, so as to cover various segments of pupillary area during examination.

A few words about *pupillary anomalies* in hysteric subjects, because there is much confusion on this point. As a rule, when either or both pupils are unusually contracted or unusually expanded the ordinary reflexes are preserved, that is, they *contract* when light is thrown upon them and when suddenly asked to fix a near object, and they expand when light is withdrawn or when the patient is told to gaze into the far distance. This is, or ought to be, a very simple matter, but in cases of hysteric amblyopia some care should be observed in making the examinations. The patient should be seated facing a half-lighted window; the unclosed eyes are completely covered with a black cloth and he is told to look, and to continue to look, as if gazing upon a distant object which has been previously pointed out to him. In thirty seconds the cover should be suddenly removed and the contractions of the pupils, or its absence, noted. The reflex contraction of the pupils for convergence or accommodation should be tested in a light as dim as is consistent with the observer's ability to see the patient's pupils. Having been told to look at an object across the room for half a minute, he is now asked to quickly fix the end of the finger held four inches from the patient's face. By means of these simple but effective devices one may often avoid the mistake of concluding that he has to deal with a pupil that does not respond to the reflexes mentioned.

I need not remind you that in hysteric amblyopia we frequently find *macropsia* and *micropsia*. Usually the patient complains of this strange symptom, probably due to irregular contracture of the ciliary muscle, but it is often worth while to test for it. A long, lighted candle is held before each eye of the patient at distances of one, four and ten feet, and he is asked whether it gets longer or smaller in size. Notes are made of his answer and the experiment repeated in a day or two.

A very common and, in my opinion, characteristic eye-sign in hysteria is spasm of the orbicularis, the so-called blepharospasm. When this is unilateral and accompanied by photophobia, or spasm of accommodation, it is almost invariably hysteric, and I believe that the majority of the spasms of the orbicularis are of this character, whether in the form of blinking or constant winking of the eyes, or where the spasm is much more marked and involves the facial muscle.

The Phonendoscope as an Ear Trumpet.—Surprising results have been obtained with deaf subjects, especially in reading aloud to them, by removing the external rubber plate of a phonendoscope, and speaking directly into the apparatus, as into a phonograph, with the tubes in the deaf person's ears.

HYSTERIA IN CHILDREN.

Presented to the Section on Neurology and Medical Jurisprudence, at the Forty-ninth Annual Meeting of the American Medical Association, held at Denver, Colo., June 7-10, 1898.

BY J. G. BILLER, M.D.

CHEROKEE, IOWA.

Hysteria is recognized as well worthy of our deepest study and best thought, by those most familiar with it. Notwithstanding this fact, and the volumes that have been written about it, we must acknowledge that in many ways we are woefully ignorant regarding it. We all, probably, feel at times as though, if there were anything which we have not found out by practical experience pertaining to this disorder, we are perfectly willing to remain uninformed.

No matter how willing we may be to call it quits, our omnipresent foe (hysteria) never will consent to that, and by appearing in new phases and new forms, as well as new combinations, forces us to learn more and more regarding it. The more we know of it the less liable we are to use some such an expression as, "Oh! it is nothing but hysteria, and does not amount to anything!" No one would want to say that of any other disease which causes so much suffering and unhappiness, and destroys the pleasures and comforts of as many homes as does hysteria. The temptation thus to speak of it is because we often feel that if the patients would, they could, control themselves, and we back up our ideas with the fact that some simple but disagreeable treatment has often caused the entire disappearance of the symptoms, and for this reason it is thought that if very much were the matter the result would have been different. These brilliant and dashing flank movements are not always successful, and we have to settle down to a regular siege, from which we often withdraw defeated, and too often our defeat is caused by our treating our foe with contempt; the patient becomes dissatisfied and passes, frequently, into the hands of some quack or charlatan, who thrives by accidentally—and probably unconsciously—knowing how to take advantage of some of the tricks of this powerful but susceptible enemy of the human family. Every physician, after having hours, days and weeks of his time taken up with hysterical patients, must oftentimes ask himself: "Where did all this host of hysterical men and women come from?" The answer to the question is: "From the mis-born, and mis-raised boys and girls of the past generation, and the children of the same class in the present generation are hurrying forward to recruit the ranks." I believe a hysterical woman can oftener be cured before she is fifteen years old than after, and it is for this reason that I wish to call your attention to hysteria in children.

This subject, as far as treatment can go, may be divided, primarily, into two classes: the first, those cases which never have hysteria till after puberty, but whose physiologic and psychologic development have been such as to leave the seeds well planted in a soil that has been carefully fertilized for their maturing. This would hardly be called hysteria in childhood, but the principal damage is done then, and that is the time when proper treatment should have been applied.

In the second division, we have the disease fully developed during childhood. It is often surprising to note what apparently slight suggestions will develop a hysterical attack in a young child. I remember a boy 3 years of age, who, upon getting up in the

morning, a week or so after having seen a man who was paralyzed in one leg go by a few times, said his leg was no good, and he could not use it and did not; careful examination was made, and nothing abnormal discovered except that he would not use that leg; he dragged it around all day, but that night, after he was put to bed, his father went in to play with him, and in the excitement of the play his paralysis disappeared, and he seemed never to think of it again. This was a child of very active imagination, and his mind had undoubtedly been impressed until he was unable to move his leg.

I have since then had two cases of partial paraplegia of hysterical origin in children. They were sisters, and of quite dull and heavy minds, whose imaginations were slow to be excited, and when the result was produced, it was just as slow and tedious to overcome. The father of these children had died of tubercular trouble, which started in the back, and one of his legs became nearly useless from sciatic neuritis. The children, after the father's death, were left in the mother's charge; she unwisely had a great deal to say about the father's sickness, and especially about his back and the inability to use his legs. The children were fond of sweet food and were allowed to indulge in cake, pie, etc.; in fact, this was about their whole diet. The living room was lighted by two small windows which were shaded by porches, and was heated in winter by a hard coal burner which was not much smaller than the room; the children's health was carefully watched by the mother; every little pain or nervousness was inquired after and examined into. The elder of these two girls (who were the youngest of a large family) had a spinal curvature, which became tender and painful; a short time elapsed before a cast was applied, and during this period she suddenly became unable to move the legs, and when put on her feet would tumble over if not held up. If held up for a little while she could partially stand by rising on her toes. Reflexes and sensation were normal, and after the application of a well-fitting plaster cast the legs became all right.

About a year later, the younger child, then about eight years old, was brought to see me for severe pain in the head; her temperature was above normal, pulse rapid; this continued for several months, and then began to improve, but all at once the legs became useless; she would not stand on them, and part of the time could not move them. Reflexes were normal; there was some pain in the crural nerves, otherwise sensations were normal. Various kinds and methods of treatment having been tried without success, galvanism was used for two months. At the end of this time she began to improve, and was soon able to be up and around; in a few weeks more she seemed as well as usual. She remained well for a year, when she had a slight tonsillitis, and before she was relieved of this her legs were again paralyzed. The battery was resorted to, and in a few weeks it had the desired result, although, to the best of my belief, no current came from the battery. No. 2 had hardly got her legs to work before No. 1 took cold and had paralyzed legs; the battery was still in the same condition, and it took six weeks to get the girl around.

This last attack was about a year ago. I have urged a better diet and more light in the living room and no conversation about sickness or sick people; but it is hard to convince the mother that anything but inheritance has aught to do with the sickness.

Paralytic hysteria, as represented by the above cases, is not so common as some of the psychic forms, but it is so marked that it attracts attention at once, while the latter often does not attract sufficient attention to be diagnosed as hysteria. I believe some of the peculiar fears of childhood are often manifestations of hysteria. I knew a little boy who would scream and cry so that he had to be taken from the room if any one began singing or playing the organ; this child afterward developed very marked hysterical symptoms.

Night terrors are undoubtedly, at times, of hysterical origin; for instance, a child three or four years of age, awoke one night screaming, and said the rats were after him; the next morning he did not want to eat breakfast in the dining-room for fear of the rats. This kept on night after night, and soon his naps in the day time were troubled with these terrors, and it was almost impossible to do any thing with him for hours at a time; regulation of diet, amusement and medical treatment, were all tried without benefit. The condition was carefully explained to the mother, who was advised to make him control himself. That afternoon he had a nap, and awoke the same as usual with the wild cry of rats; he would not sit on a chair or stay in bed or even be quiet in his mother's arms. No man with delirium tremens ever had greater fear of snakes than that poor child had of rats; the mother told him in a very decided tone that he would be whipped if he did not stop, and then, as he did not mind, he was spanked. This forced him to control himself for a few minutes; then he began again, and the spanking was repeated. This had to be done two or three times, but finally the child was forced to control himself, and was never troubled that way again. This may seem cruel treatment, but it became necessary, in some way, to force the child to exercise sufficient will-power to overcome his excessive imagination. The boy several times since has shown marked symptoms of hysteria, but owing to the care he has had has completely outgrown them.

I do not wish you to understand me as advocating whipping as a cure for hysteria, but in these psychical forms, the child must be brought, in some way, to control itself and taught to continue this, and there is no question but what fear forces not only children but grown people as well to keep their imagination and desires well in hand. The cases which require punishment are, I believe, rare, but all these unfortunate children should have a strong hand to help guide and direct their imaginations.

One of the best instructors in self-government is the association of the child with other children; our public school life is valuable for that if for no other reason; there is no question but that children are often abused and imposed upon, still they soon learn that they can get along better if they behave themselves, and that if they wish to enjoy their play they must be agreeable to their playfellows. This is an excellent discipline, although it may occasionally make the parents a little angry when they think their child has been used unjustly—as it often is—but we must all expect to suffer some for the public good. The rough plays that bring home torn clothes and bruised bodies and limbs are not to be looked down upon. It is the freedom of the boy to indulge in any sort of physical recreation that his desires may dictate that has much to do with making his sex less liable to hysteria than the sex of his less fortunate

sister. The boy, as soon as he is old enough to be around, is dressed so that he can run, jump or turn heels over head; in fact, his movements are not interfered with in any way, either by dress or custom, but how is it with his sister? Whatever of liberty there is left after the method of dressing is taken from her by custom and the fear of being considered immodest. I think the little girl was right, who, when reproved for turning heels over head in the front yard, said, "if people did not want to see her, they must not go by when she was turning heels over head." She had the true sense of woman's rights—the right to be healthy and enjoy health in physical recreation.

Children should be well fed, and these neurotic children, as a rule, are poor eaters, both in quality and quantity. They should be confined to plain, nourishing food, and then forced to eat it. People often tell us they cannot get their children to eat, and are surprised when you insist upon their being made to eat; but I have had the pleasure of seeing several of these rapidly improve under judicious feeding. One case I will briefly describe: She was a delicate, nervous little girl, who was thin and anemic, unable to sleep at night because of nervousness. She wanted no breakfast, unless it were a cracker or a cookie, scarcely any dinner excepting dessert, but at supper she generally did eat a little better. She was absolutely forced to eat a large dish of oatmeal and milk, without sugar, each morning; a dinner of bread and butter, potatoes and eggs or meat, and drink a glass of milk, no dessert; for supper, she had a dish of oatmeal and milk, bread and butter and some kind of sauce, generally stewed fruit, either dried or fresh. Besides this diet she was allowed plenty of fruit, and was sent early to bed. She has been on this stuffing treatment for nearly two years, and is now strong, does her school work easily and well, never has headache, sleeps well, except that she gets up early in the morning. This child's poor health was attributed to going to school, as is done in a number of cases, and the children are kept out of school. I think there is no question but that their school work is too much for them in their physical condition, but too often this condition is caused more by the improper home life than the school life.

Neurotic children suffer greatly from competitive examinations at school, and from the extra work that is often imposed upon them in preparing for school entertainments—especially in preparing for public recitations. I knew one young girl of 13 or 14 years of age who was standing her school work well till she was selected for an important part in some special exercise. She was impressed with the importance of her part, and from the careful drilling she got she became frightened and nervous, and finally ended by going into a hysterical faint after one of these drills. It was a year and a half before she was able to go to school again, and she had during that time vertigo and other hysterical manifestations. At the end of this period she started to school, but she has never been allowed to do any but regular work, which she has accomplished with ease.

I have not referred to the medicinal treatment, for it has been quite thoroughly impressed on my mind that drugs are seldom indicated, and their value is questionable. The price of healthy children is the same as that of Liberty—Eternal Vigilance—and unless parents and physicians are willing to pay that price, we can not expect to avoid hysteria and many of its relatives.

ORIFICIAL IRRITATION IN RELATION TO NEURAL DISTURBANCES.

Presented to the Section on Neurology and Medical Jurisprudence, at the Forty-ninth Annual Meeting of the American Medical Association, held at Denver, Colo., June 7-10, 1898.

BY GEO. V. I. BROWN, M.D., D.D.S., C.M.

DEAN AND PROFESSOR OF ORAL SURGERY, DENTAL DEPARTMENT MILWAUKEE MEDICAL COLLEGE.
MILWAUKEE, WIS.

It would seem, upon consideration, that many operations brought forward by the gynecologists during the last few years for relief of so-called reflex pains and other nervous disorders, particularly neuralgia and migrainoid headaches, have not given the relief that was promised for them. The same is undoubtedly true to a considerable extent in regard to the rectal surgeon's efforts, and notwithstanding the fact that deviating septa and hypertrophied turbinates have freely given off their offending portions, there still remain many who suffer constantly without a hope of relief; and in directing your attention into a new channel with regard to etiology and treatment of these conditions, I would urge the fact that, with a high nervous organization and free distribution of nerve-supply quite as complex as that of the other orifices referred to, the normal mouth has thirty-two teeth as additional predisposing factors, each with its own separate nerve-fibers from the wide-spreading carrier of sensation—the trigeminus. In addition to these connections each root is surrounded by a highly vascular peridental membrane, also in close connection with the blood- and nerve-supply, making it not unreasonable to suppose that all these taken together would offer a very frequent source of irritation. Considering also the fact that through caries the pulps of these teeth and the nerve elements they contain are often exposed directly to external irritants, the etiology factors, particularly with affections within the range of the direct nerve-supply through which they carry the sensation, ought in a large number of cases to be found to be within the oral cavity. That this is often true without being suspected, through misleading symptoms, the trouble being treated as having its origin in some other of the orifices, will be shown, I think, by the cases described later.

Literature upon the subject of this and kindred disorders is very vague. We find neurasthenia, anemia and numerous other emias, held in a general way to be reponsible, and the recommended treatment beyond certain limitations, also becomes very general, depending chiefly upon general constitutional care, which is all very well so far as it goes, but as a rule the patients suffer on just the same. It is evident to those sufficiently interested to be more than casual observers that in close study of the symptomatology of those affections, with a view to discovering certain definite causes of irritation and the mode of procedure best calculated in each particular case to remove the etiology factors, lies hope of relief. During the last few years my efforts have been directed to the study of certain peculiar forms of trifacial irritation, particularly one form of which little or nothing in the way of description seems to be extant in the literature of the subject.

Without attempting to go into a general or even a partially detailed description of the various possible irritations from within the oral cavity, I desire to treat of what I have found to be a very common associate of neural disorders. It is a noticeable fact that in the

mouths of all those so affected, wherever the natural teeth remain, their occlusal surfaces show that constant grinding and rubbing has abraded them, through the extreme pressure brought to bear during the paroxysms—if the pain be paroxysmal occurring in an intense nervous state—the result of hours of painful suffering or other like conditions. This has frequent mention by writers as noticeable among those who suffer from such disorders, but in no instance do I find where an author has thought fit to reverse the order of things and make the habit of the jaws, which is responsible for this condition, one of the etiologic factors in bringing about the disease, rather than a result, as it is generally held to be. Last year, before the Section of Stomatology, I described this hyperkinetic condition of the muscles of mastication and explained how irritation of the brain-centers governing these muscles, whether as a symptom of other neural disturbance or vice versa, would produce the same result, namely, an irritation of the peridental membrane surrounding the roots of the teeth, and how, through their apical foramina, this irritation might be communicated to the many branches of the nerve, after which, as is well understood, the point at which that result expressed itself in pain, muscular spasm, tenderness of neuritis, hyperesthesia, anesthesia, or whatever the effect might be, could be reflected anywhere along the path of the nerve among its associates. Certain forms of this peridental inflammation and the resulting pain are quite familiar to dentists, but that there was grave trouble frequently caused by other forms of this affection, with which neither they nor physicians were commonly familiar, I have long been satisfied, and in the paper referred to I described a number of cases of extremely aggravated pain in the head and face, which were cured, or to a considerable extent relieved, at my hands, by the simple method of grinding the crowns of the particular teeth affected in such a manner that they could no longer be brought together. Since the writing of that paper, however, and during the last few months, through my connection with Trinity Hospital in Milwaukee, another form of this particular trouble has come to my notice in several cases, with symptoms such as are commonly ascribed to reflex expressions of uterine diseases, and it is to these that I purpose calling your attention.

In order that something may be understood of the manner of the operation of the jaws, which makes this possible, a little description of their anatomic relations, with particular reference to the development of this idea seems to be in order. Through the pterygoids a lateral grinding motion of the jaw of man takes place, which if pursued at night is easily noticed, and usually attention is called to it. If, however, the masseter and temporal muscles are called into unusual activity, the result is that the jaws are pressed firmly and tightly together, with a force varying in individuals from 200 to 270 pounds. With the jaws closed normally and the occlusion perfect, this force would be comparatively equally divided among the whole number of teeth. If, however, as usually happens in these cases, the jaws be shifted a little to one side or slightly forward or backward, then certain portions of individual teeth are brought together, and they alone must bear this tremendous force. Ordinarily the membrane surrounding the root is capable of withstanding a considerable amount of pressure for a considerable length of time. But by the continued application of this pressure, especially when weakened by

other more general conditions, as of circulation or otherwise, this power of resistance becomes impaired and then one of two things must result—either a local disturbance made manifest by elongation of the tooth and soreness to pressure, a not generally serious affection, accompanied sometimes by localized pain, usually comparatively easily remedied, or as I have believed, a direct communication of this irritation to the larger nerve trunks, to be by them carried to other parts. It has been recently proven that the old idea—as given in Gray's and other anatomies—of a direct communication of artery, vein and nerve, from the apical foramen to the main trunk of the nerve, passing along the jaw, is generally, if not always, incorrect, and that there is a more complex nervous connection with nerve filaments extending directly from this membrane to the main nerve supply, and this scientific histologic demonstration is directly in line with my own clinical observation, because it explains at once what I believe I have demonstrated to be true: that any or all the nervous symptoms generally recognized can be the direct result of peripheral irritation through this peridental membrane. We are all familiar with the much-written and widely understood neural disturbances consequent upon eye-strain, but whoever heard of neurasthenia, hysteria or neuralgia resulting from jaw-strain, and yet this is exactly what does occur. If the use of certain muscles and the straining of those muscles can cause neurotic symptoms through irritation of the optic nerve-supply, why can not the continued application of hundreds of pounds of force directly to certain other branches of the nerve through which sensation is transmitted do so equally with the other part. This theoretic explanation is, I believe, borne out quite fully by the following cases which, for example, I desire to describe:

Case 1.—Mrs. ——— complained of a general debility, loss of strength and poor circulation, and suffered intense pain at rather short intervals, which finally became shorter until the pain was almost continuous between her eyes at the base of the brain and in the vicinity of the ear upon the left side. Three operations by gynecologists, who had mistaken her symptoms for reflex pain due to some womb disorder, left her rather worse than better. The treatment of certain inflamed conditions of the pulps of her teeth and maxillary sinus, and a correction by grinding the surfaces of tooth crowns, giving evidence of receiving rather more than their share of the wear and tear has given her, at least for the few months past since the operation, complete relief.

Case 2.—Mrs. ———, a very great sufferer, pain in eyes, back of the head, which during severe paroxysms was severely felt also in the back, arms and leg, had become almost a hopeless neurasthenic. The birth of the last of her five children was coincident with the onset of the severe symptoms and naturally led to treatment for laceration and endometritis, but without result. The abraded crowns of several teeth and the set expression during pain facilitated diagnosis: the treatment applied was to grind the occlusal surfaces of the affected teeth until they could not meet in occlusion, and treatment of pulps of the teeth that were irritated, resulting in complete relief from pain and a generally improved condition.

Two cases were reported in the paper before referred to, one in which hyperesthesia of the lower lip and chin was instantly relieved by the extraction of a bienspid tooth of a woman who had been treated, as she said, "for falling of the womb"; and another, a girl about 17 years old, whose extreme suffering for about eighteen months was finally relieved by grinding down certain teeth, irritated by grinding at night, found to be the probable result of sexual excitement as shown by a history of the case.

Many similar instances might be recited in which the symptoms of pathologic oral conditions have been

confused with those of the eye, ear, nose and rectum, as well as of the vagina and uterus, but the present purpose is chiefly to call attention to the fact that this habit of the muscles of the jaws is of extremely common occurrence—in fact, nearly always an active feature of nervous states—for if caused, as sometimes happens, by overstimulus of the centers controlling those muscles, the result of some etiologic excitement elsewhere, then the effect is simply to increase the severity of symptoms; on the other hand, it may be the irritant, and solely responsible, but in either case the simple attention necessary to correction of the difficulty is a matter of first necessity in the treatment of a large majority of sufferers from functional and other disorders of the nervous system.

NERVOUSNESS AN ELEMENT IN HYPERPYREXIA.

Presented to the Section on Neurology and Medical Jurisprudence, at the Forty-ninth Annual Meeting of the American Medical Association, held at Denver, Colo., June 7-10, 1898.

BY C. C. HERSMAN, M.D.

Lecturer on Mental and Nervous Diseases, Western University of Pennsylvania, Medical Department; Physician to St. Francis Hospital, Insane Department; Alienist and Neurologist, South Side Hospital, Pittsburg.
PITTSBURG, PA.

Temperature, from Hippocrates down, has been recognized as a factor in disease. In the present paper the topic is to be discussed with reference to the explosive (nerve-storm-like) and sudden elevation of temperature under certain mental impressions or conditions.

Musser attributes the stability of temperature to the central regulating apparatus, called the thermotoxic apparatus. This aggregation of forces is under the control of the nervous system, either through the motor or special nerves which pass with them to and from definite centers in the brain, called heat centers. He claims that the elevation of temperature is due to the increased disintegration of nitrogenous tissue. It has also been said that the high range is caused by the taking in of more poison than is gotten rid of, or, to give bacteriologic zest to the expression, the microbes are in competition with the corpuscles of the blood.

High temperatures are not so dangerous, or so uniformly fatal, as low. Da Costa records a recovery from a temperature of 110 F. in the axilla, following cerebral rheumatism. Teal reports a case of recovery from a spinal injury with a range of temperature of 112 to 114 F., which continued for days. Dr. J. B. Murdoch of Pittsburg, formerly Dean of the Medical Department of the Western University of Pennsylvania, admitted a case to the Western Pennsylvania Hospital Dec. 13, 1893, whose temperature on the eighth, ninth, tenth and eleventh days was respectively 112, 114.8, 119 and 120 F. His patient had hysteric symptoms and he, with others of the staff who saw the case, decided that the hysteria was the cause of the high temperature. The cause of these high temperatures is mere conjecture. The increased disintegration of nitrogenous tissue and the microbes in competition with the blood corpuscles can not be relied on.

Experiments upon dogs have shown that to irritate certain centers of the brain will control temperature, while destruction of the center will cause a high rise. I have thought that a hyperesthetic condition of the

heat center might answer for the cause, but according to the irritation theory, nothing short of a paralysis of the center could cause the rise, while the hyperesthesia would control it. In the following cases the last thing mentioned could be the only plausible one to me:

Case 1.—K. R., aged 21, American, nurse. Disease diagnosed as spinal meningitis. Admitted to South Side Hospital Dec. 4, 1897. Family history negative. Personal history, typhoid two or three years prior. During the course of the disease she complained severely of a pain in back of head. Delirium marked. Three months ago confined to bed with severe pain around cecum and caput coli, with some inflation. No elevation of temperature, but nervous, with inclination to hysteric symptoms.

Present trouble began with severe headache, with boring pain in back of neck, followed by numerous chills and muscles of back of neck rigid, with head slightly drawn back, tenderness along spine and mild delirium. Retention of urine. At times evening temperature 107 F., but was promptly reduced in a very few minutes with ice sponge. Antipyretics had little effect. Pulse at times very weak. On the seventh day the temperature was highest, 118 F.

At times the temperature would drop from 110 F. to normal in a very few (twenty) minutes without interference, but mostly the sponge bath was resorted to with very prompt effect. Usually when she had the high temperatures she had marked hysteric symptoms. The fever always abated most rapidly when treated by those in whom she had most faith and liked best. A visit from friends would provoke an attack, seemingly, to me, to show how sick she was.

My diagnosis differed from those who had preceded me, as I could see nothing but a very exaggerated nervous condition attended by hyperpyrexia and hysteric symptoms. At the end of fifteen days she was sent home.

Case 2.—Lizzie N., aged 29, Irish, domestic. In United States eight years. Admitted to South Side Hospital of Pittsburg, Dec. 10, 1897, her disease having been diagnosed articular rheumatism of one week's duration, which was ushered in by a chill.

On admission temperature 99 F., pulse 102, respiration 24. Joints sore and very tender, especially the knees. On the second day after admission the temperature became normal. On the fourth day 104 F., eighth and ninth days normal. On the thirteenth day normal, but on the fourteenth it rose to 106.2, pulse 80. On the eighteenth day 110.9, pulse 80; twenty-third day 11:30 A.M., 110, but at 2:30 P.M. had dropped to 99, pulse 80. At various times from the eighteenth to the twenty-third day the thermometer registered 110.

On the thirty-fourth day of the disease the register was 112. On the thirty-fifth day at 11:30 A.M. I took her temperature under the tongue at 116 F., with a pulse of 80 and a cool skin, and twenty minutes after I left the ward it was registered at 102 by another thermometer. On the forty-second day after admission the thermometer registered 118.4. Her temperature for the past few days ran along from 105 to 108, occasionally down as low as 104, and once to 103. This continued up to the sixty-ninth day, when the temperature dropped to 99, following a chill, but soon to return to its old haunts, 108 to 110. This high range continued until the eighty-sixth day, when at 3:20 A.M. it registered 98, but again went back to 107.4, which continued until the ninety-third day, when she became dissatisfied and asked permission to leave the hospital, which was granted.

She left with a temperature of 104.8 and walked with slight assistance to the street-cars, three squares away, but on the evening of the same day she returned slightly intoxicated and asked to be readmitted. Her temperature was then 97.4. On the second day after readmission her temperature was 108, on the third 110, on the fifth 112.4, on the sixth, A.M. 97, but at 1:20 P.M. was again at 111.2; on the seventh 97, but on the eighth was 108, at which time she was sent out of the hospital, 101 days after her first admission.

She went to the home of her former employer, where she remained for about ten days, going about the house, and occasionally going out. On attempting to alight from a street-car she broke her ankle and was sent to a hospital. Her improvement has been continuous and her temperature has never been above 99.4 F. Usually it has been normal. In the first hospital her rest at night was very much broken. Sometimes she would sleep all night, at others lie awake until 3 or 4 o'clock in the morning. If the interne not in attendance on her would administer her hypnotic she would be likely to lie awake all night watching for "her doctor," to find out whether the

medicine was correct. Seemingly, the hypnotic administered by the wrong person destroyed the hypnosis. If she were piqued or worried the temperature would rise. At times when she was perfectly quiet, skin cool, pulse normal (or almost so), her temperature would be highest. These temperatures were

were completely overpowered (paralyzed), the radiation possibly interfered with, consequently the heat storage. Specimen sections of temperature chart give an idea of extreme fall and rise.

taken with both fever and bath thermometers, under the tongue, in the axilla and in the rectum.

During this period of hyperpyrexia she could sit up in bed, at times on a chair, and she always expressed herself as relieved and rested afterward. At times she was led about the room, which seemed to have more effect on her high temperature than drugs.

Like all the Celtic race, she was very much afraid of dying, and when most agitated her temperature was highest. After a talk with her, an examination, or a pretense to such, and an assurance that she was better, her temperature would usually lower. One nurse she disliked, and her presence would aggravate her fever.

Query: What was the disease in the two cases reported? My diagnosis was hysteric hyperpyrexia. The tender joints in the one, and the tender spine in the other, were hysteric symptoms, rather than rheumatic or meningitic. The emotional centers were so overburdened or exaggerated that the heat centers

DISCORDANT SOUNDS A MENACE TO NERVES.

Presented to the Section on Neurology and Medical Jurisprudence, at the Forty-ninth Annual Meeting of the American Medical Association, held at Denver, Colo., June 7-10, 1898.

BY JOSEPH A. GUTHRIE, M.D.,
P. A. SURGEON U. S. N.
MEMBER OF THE ASSOCIATION OF MILITARY SURGEONS OF THE UNITED STATES, ETC.

The reason for selecting this subject is because of a number of inquiries made to me personally, regarding the why and the wherefores relative to it; and as in some instances I was at a loss for ready answer, it behooved me to place my theme in the hands of those whose learning and experience I am sure will help me out of a quandary, rather than turn a critical eye upon

it, and so, by making public their demands my inquisitors may benefit.

It is needless to record statistics in speaking of this every-day evil whereby our tympani are assailed, and which by becoming inured deceive us into believing there is no particular harm done. Even though statistics were brought forth, what objections might arise to the statement: "noises create a disturbance of the nervous elements to the degree that they are vouched a place in the category of causations of disease." Therefore, it is the object of this paper to reason from pure observation, and attempt a clear analysis for the judgment of the profession, as to whether the above statement is worthy of consideration, and embody in its entirety a question answerable by that same honorable body. Then let us lay down for consideration some instances in our experience: certain mental records which have sunken into the fertile lands of our memory, making their impressions accordingly. To begin, shall we admit that when a healthy condition of the nerves exists, the greater amount of nervous shock we bear with impunity, but by frequent repetitions the less able are we to withstand the resulting jar.

We have acquired from nations now fallen into decay and almost, if not entirely, obliterated, an intuitive knowledge of many of our present customs, not to mention the suggestions and realizations of innumerable arts, inventions and sciences, so useful to mankind. These customs we adapt unwittingly, as new wants present. Relative to this instinctive tact of man, should we go further—beyond the human—is it not observed in a few peculiarities, that even the lower animals lend their aid in suggesting means to us? Call to mind the quail when disturbed in its foraging: by the suddenness of flight, by the noise of its wings in rapid vibration, it will disconcert the disturbers. If the enemy is startled the birds escape; some of us in our maiden attempts afield may have been vividly reminded of this, if we forgot to use our fowling-piece before the game was beyond gunshot. Prior to long-distance warfare, a pretty successful scheme (shall I call it bluff) was in vogue among the Chinese, which upon the superstitious children of ignorance, played a prominent part in enhancing China's length and breadth. These people calculate upon fright as a means of conquest, thereby saving the lives of friends and foes alike, at the same time gaining the end in view. A bloated, elaborately painted wind-dragon, then may account for Chinese supremacy and their populous empire. The tiger roars, so it is said by some, with his leap upon the exquisitely high-strung fawn, thus gaining a moment's hesitation, and before the prey is in motion his talons grip its tender flesh.

For no rhyme or reason, in these modern days, with every new invention there accompanies a new noise, so to speak. The snorting, bellowing locomotive engine replaces the musical post-chaise; the screeching, whistling steamer has supplanted the galley and the sailing craft, teeming with romance. And with the explosive fire-arm comes an innovation upon the bow and arrow. The ancients may not have been so cleanly, but they certainly were less noisy. I was told when at Gibraltar that during target practice and drill with the great guns, the loss in frangible property amounts to not a little sum; and I may instance a dozen other experiences wherein noise—and not a woman—was at the bottom of misfortune. I once

knew an octogenarian farmer, who, when asked why he did not take a lantern in traveling over lonely roads at night, replied that he carried a pistol, which would give him light if needs be in case of attack; he evidently did not wish to attract attention to himself unless waylaid, and then he had light and sound stowed away ever ready. In certain land-locked harbors I have heard the inhabitants complaining of tugs and other noisy boats blowing off their whistles, especially those known as calliopes. The would-be waggishness, or to-what-purpose desire of these tug captains, deserves a compensation suited to the perpetrator. Have not the cartoonists discovered the tired and irritated visitor from the provinces, racking his brains in the uproarious city, unable to collect his faculties; and has the father, nightshirted and capped, marching the colicky infant in the small hours of the night, escaped this artist's humorous vein? Little mirth it would be if the tables were turned, were it possible to do so. All these things call to light the necessity for a scientific investigation of the question of useless noise.

In a few cities it has been proposed passing an ordinance against the ringing of church bells—this may to some disturb the "day of rest"—but why not include in this an ordinance for week days: the shouting of street hawkers, the clanging of other varieties of bells, the steam whistle of the factory, and last but not least, our young vender of the daily press, with his shrill tenor announcing the never-ceasing "extra!" How much better is the silent signal, both in war and in peace; take the popular foot-ball game and we find that the teams under better control are those who have mastered the silent signals of command. One reason the modern war vessel is so deadly, may be said to be because it is absolutely as accurate as a floating battery can be; and is not the cause of this accuracy due in great measure to the silent commands sent from the conning-tower by the captain to each of his subordinates, shut off from him and each other by walls of steel? When an order is indicated upon a dial manipulated by electric transmission one receives the same in a tranquil state of mind; but if the order is shouted at him by one, two, three or more in rapid succession (as of yore), then there is excuse for confusion in carrying out commands. In this treatise a good deal is left to the imagination, and my theme, I must admit, is undeveloped; so I beg much leniency for my awkward manner of launching it forth on a scientific basis, and ask those interested most to consider it as merely an advance guard for a subject worthy better forces.

MORAL INSANITY IN INEBRIETY.

Presented to the Section on Neurology and Medical Jurisprudence at the Forty-ninth Annual Meeting of the American Medical Association, held at Denver, Colo., June 7-10, 1898.

BY T. D. CROTHERS, M.D.

SUPERINTENDENT WALNUT LODGE HOSPITAL, ETC.
HARTFORD, CONN.

The term "moral insanity" is applied to a class of symptoms about which much difference of opinion exists. Formerly this was a veritable battle-ground between metaphysicians and alienists, but latterly this has subsided, and the questions now in dispute are differentiations and exact meanings of terms. I shall limit my study of the subject to certain well-marked symptoms which, taken alone or associated with other symptoms, appear to have the same signifi-

cance. Moral insanity is marked by a low sense of right and wrong, and by conduct which does not recognize the rights of others, or duty and obligation to any one. The ethical sense and consciousness of the relation to others, of truthfulness, of honesty, of respect for the good and true, for law, or for the opinions of others, is enfeebled or wanting altogether. Such cases may not exhibit marked intellectual weakness and may appear to have average judgment and discrimination in the conduct of affairs; yet have no moral sense of obligation to do right and to be truthful and honest to others. Such men are intriguing, deceitful, dishonest, taking advantage of every opportunity to gratify their most selfish desires irrespective of all consequences to others. The higher levels of cerebral development, which are the altruistic sentiments, the capacity to recognize and adjust conduct to the general good of all, are wanting. What is called character motive, purpose in life, or the morale of the man, his relations to others, are all the last formed elements of brain growth. Insanity, which is confined to these psychic centers, is well established. Without doubt other parts of the brain are affected, but they do not appear, except from a careful study. I think it also well established that sudden changes of character are always due to changes in the organic activities of the brain centers. It is asserted, and defended with many good reasons, that consciousness is an element of the brain which recognizes the higher relations of right and wrong, of duty, and all the higher psychic claims of justice and truthfulness and the relation to our fellow-man. The higher this development the stronger the man, and its absence or feebleness approaches imbecility. The general term "character and morale" describes this best. A veritable insanity in which this part of the brain was the most seriously affected has been described over a century ago. All the authorities recognize it but attach widely differing importance to its meaning.

Cases like the following are not uncommon, and probably illustrate this condition more clearly than by theories: A. B., a physician of average ability, culture and good character, with an excellent reputation for honesty and sobriety, began gradually to be untruthful, intriguing and dishonest. He made out double bills and denied payment even when his signature on receipts was shown. He exaggerated his business, drove his children away from home, was cruel to his wife and tyrannical to every one under his care. This increased and was not associated with any apparent intellectual changes. He was not passionate or emotional, but cool, and gave no explanation for his conduct. He became involved in forgery and assault, and died before the trial from some heart failure. This was moral insanity in which the physical basis was not recognized.

In inebriety these symptoms of moral defects and insanity are common, no matter what the conditions and standing of the person may be. It seems to follow the poisoning from alcohol inevitably, and in some cases very markedly. Two classes appear very prominently, one with heredity and the other apparently acquired. Wherever there is a marked history of heredity, of alcoholic parents, or of neurotic degenerate ancestors, a feeble or deficient consciousness of right and wrong is found. Alcohol used continuously retards growth, diminishes vitality, and prevents development. Drinking parents have deficient vitality and are unable to transmit to the next generation full

normal vigor. The last and highest formed element of brain power—consciousness—is the first to suffer from alcohol. Hence drinking parents can not have children with full normal consciousness. This faculty will be wanting or very feebly developed. This is the rule to which the exceptions are rare. This defect may be associated with much intelligence and intellectual capacity and power to cover it up.

A man prominent in the political world is in private life devoid of all sense of justice, of right and wrong, and duty to others. He is untruthful and dishonest, and when his own interests are in conflict, will sacrifice any person or principle to gain his ends. He is of unsound intellect, yet able to pose behind a mask of honesty often acting honestly and talking of duty, but always from the most selfish motives. He is married, has a position in society, but keeps mistresses, and is open to every suggestion that promises his personal and selfish gratification. His parents were wine-dealers and drinkers, both of them waiting on customers over the bar. Only one child grew to manhood, and entered politics as a trade. He is temperate, but a moral paralytic, or a moral maniac with capacity to conceal this condition. A man who became one of the great swindlers and forgers of the day, but who was able to keep out of prison by intrigue and cunning, came from drinking parentage. To his associates he is known as without any sense of duty and obligation to any one and is a literal Bedouin.

That these conditions are due to inheritance is apparent from the following: A boy with excessive drinking parents was taken in infancy and educated in the most careful way. All the higher faculties were cultivated to an unusual degree, and he entered the church as a brilliant clergyman. He was found to be untruthful in regard to himself, suspicious of others in matters of personal reputation, and grasping even up to the border of theft on many matters. The collections in the church had to be kept out of sight and always suffered if they passed through his hands. He became involved in spreading scandal, and seemed oblivious of the danger of such conduct, and broke up the church by his irregularities. For ten years, until his death, he was in continual trouble with every church he was associated with. Here the evidence was clear that he had inherited defective consciousness, which no training or surroundings could overcome.

In cases where inebriety has been acquired by accident, contagion, surroundings and conditions of living, these moral insanities vary widely and are not so general, but are confined to particular things. In one case excessive untruthfulness and dishonesty in all business relations was associated with sympathetic tenderness to all his associates. In another, intense suspicion and doubt of the honesty of others was associated with excessive desire to be truthful. Another was excessively immoral, seeking opportunities for sexual intercourse at all times, was hysterically religious and anxious for the conversion of the world. Another was intriguing, secretive, treacherous and uncertain in his talk and conduct, and yet lived a moral, upright life. These are almost infinite in variety and manifestation, and all show profound changes in the moral faculties. The more common forms are illustrated in this case: A. B., a business man of good reputation and standing in the community, began to drink after a protracted illness from typhoid fever. Two years later he was an inebriate.

His mind continued bright and clear, but his character had changed. He was deceitful, suspicious and slanderous. He thought his sons and clerks were robbing him and that his wife was in league with them. He had his books examined by an expert and was in doubt when they were found correct. He told falsehoods about his business and family, and grew more and more egotistical about his mental capacity to reason and decide on all matters. He was harsh and tyrannical to his wife at times, lost all pride of character in the community and sense of duty to others. He was exacting to have anything done for his own interests, and oblivious of others and their feelings and tastes. As a patient, he was intensely selfish and grasping, even up to theft; was fawning and obsequious, promising everything and doing the opposite. He imagined evil of every one and told malicious stories without any foundation, then denied them. He was always reporting others as doing wrong, and supposed every one to have only the basest motives. He stopped drinking, but thought all others drank and concealed it. This man left the asylum and is yet sober after some years, but is morally insane.

In a general summary of the common symptoms following the use of alcohol, untruthfulness, or a low respect for their word, is most prominent. A man who previously took pride in the correctness of his promises and statements, will become indifferent, promise anything, make any statements, whether true or false. A man previously honest and trustworthy will be found doing dishonest things, cheating persons, taking advantage in little matters, and failing to act fairly in the interest of others. Then follows suspicion of motives and conduct, doubting the honesty and purity of persons. This deepens into delusions of intrigue and deception of others, extreme pessimism and doubt of everything, or a state of mind which may be called "combative erythiasism" follows, in which the distress of others is pleasing. This is manifest in malicious criticism and scandal, pointing out faults and magnifying them, apparently enjoying the knowledge of the dishonesty and malice of others and the irritation which follows from the publicity which they give to it. Sexual conduct is without restraint; the ties of family and duty become less and less; intense personal selfishness to gratify every impulse at all expense follows. The taste for gambling and speculation becomes a morbid impulse, often to retrieve their waning fortunes. Recklessness in the use of money, throwing it away without motive or purpose; or extreme parsimony to hoard it, and grasping selfishness, equally unseasonable, are common. As in other insanities, exaltation of the *ego* follows, and intense confidence in themselves and their power of reasoning and ability to do anything possible is present.

Many persons who exhibit all these symptoms appear to be but little changed in other respects. They carry on business, seemingly make plans and execute them, and appear to casual observers the same. These insanities seem to concentrate into particular lines or ranges of thought. Consciousness of truthfulness may be almost entirely absent, and in other respects appear the same. Moral recognition of the higher truths of faith and trust are gone, yet he may act sensibly and be a church member. In one case an inebriate lawyer doubted the honesty of every one and thought no one was pure or had good motives,

and yet he acted on what seemed the opposite. It was surroundings alone that held him; the restraints of society covered up an insanity which only needed a favorable opportunity to break out. In another case, a teacher who had drank many years, became a secret thief, purloining everything which he fancied, and when likely to be detected, restoring it in some mysterious way. He appeared and talked honestly and yet when not observed took advantage of every opportunity to appropriate anything that came in his way. A number of cases of inebriates have been reported where this kleptomaniac impulse took on certain peculiar forms. Thus one man when drinking stole bibles, another jewelry, and when discovered gave it up freely. One man stole washtubs. A woman inebriate always took aprons and towels; another man stole soap, and so on. The most unusual and unreasonable things were taken, concealed, and given up freely without any sense of the nature of the acts. One class of inebriates exhibit this insanity in malicious slander, another in extreme suspicion, another in vindictiveness to resent real or imaginary evils, another in immorality and impurity of act and thought. Many of the chronic cases exhibit all these phases in one. The oft-repeated expression that "inebriety is criminality" is true in a general sense, when criminality is understood as a course of conduct in which duty, right and obligation to each other are ignored. The inebriate has physically defective senses; he is not able to adjust himself to the outside world correctly, because his knowledge of their relations is imperfect. His power of reasoning is also deranged, because the impressions from without are faulty and the integrity of the normal action of the nervous system is impaired. The coarser lesions are well recognized and can be traced in all cases. Beyond this, conduct indicates the higher moral defects and changes. Psychological changes, as loss of pride, of character, of honor, respect for the truth, of duty to others, low motives or no motives, extreme pessimism, are the first and common changes which lead up to criminal acts. The paralyzing action of alcohol is first seen on the moral brain of consciousness; in the dullness and defective workings of the higher functional activities. The changes observed when a man is under the influence of spirits, is vaguely called the removal of the restraint of reason, and dominance of the animal impulses—the brute triumphing over the real man. In reality it is palsy of the consciousness, a cutting off of some part of the higher brain, and consequent confusion of the lower brain and its workings. Impressions and their meaning are confused and obscure; the higher relation of events and conditions of life are unrecognized. It is asserted that 3 per cent. of all persons born are without normal consciousness of right and wrong and their relations to others. They have retarded brain development. The part of the brain which constitutes the moral control or consciousness of the higher duties is wanting or undeveloped. Such persons are defectives, and insane in the general meaning of that word, and like dementals, are incapable of normal healthy adjustment to the relations of life. When an apparently normal state of this brain function has existed and then a great abnormality follows in thought, word and conduct, disease is present. Comparison of the conduct and character of inebriates before alcohol is used and after they become habitués, brings out some startling facts that are unrecognized.

From the lowest type of a demented inebriate on one side to the moderate drinker at meals and the fashionable clubman, there is a distinct relation and chain of cause and effect. The clear moral insanity of the one is traceable to the other without any sharp dividing lines. The moderate drinker and clubman who proves to be the defaulter, or who is involved in conduct that is criminal, or who becomes a principal in crime, is suffering from disease differing only in degree from the degenerate inebriate tramp. Moral insanity is a very prominent phase of all inebriety. Its absence in any given case is always an exception to the rule. A man with a high moral development, after he becomes an inebriate may retain the form and externals of his previous character. He may be more emphatic in his display of some qualities, such as religion, truthfulness and duty, and yet in other matters be oblivious of all obligation and duty. One such man, who prayed for inebriates and lectured on temperance, carried on an intrigue and sold his influence to the highest bidder. Another man acted as an agent for the sale of stolen goods, and at the same time carried on a great reform revival; and another was engaged in gold mine swindles, while lecturing every night for temperance. The moral insanity was called hypocrisy and in a legal phrase was malicious, criminal and vicious. In reality it was degeneration and disease, the breaking down of one part of the brain while the others remained apparently clear. In our Civil War a noted general was drunk to excess at times; previously he was noted for his hearty frankness and honesty, but was found unreliable, intriguing and failed when needed most. He showed petty weaknesses and untruthfulness, with malice that was unknown before in his character. He finally died a moral wreck after the war was over, having become almost criminal in his thoughts and acts. A clergyman became a secret inebriate and later became involved in a low intrigue and was turned out of the pulpit. He was insane, his consciousness became palsied and for a time he taught ethical truth automatically. The possibility of one part of the brain being affected and the rest doing normal work, and this condition being concealed, is a reality which every experience confirms. The very close relation of one part of the brain with the other makes it impossible for health and disease to exist together, and yet moral insanity may be present and be concealed from general observation. A study of conduct will reveal it and a comparison with previous conduct will show its growth and development. The inebriate who has lost pride of character and sense of duty and obligation, truthfulness and honor, may seem to be the same in many ways for a long time, but sooner or later this moral diseased condition will spread and his whole organism show degeneration. I shall conclude this brief study with the records of two cases which have occupied public attention and been the topic of bitter discussion.

Case 1.—John Blank. Father was a strolling actor of irregular character and an inebriate. He married a woman of average ability from a good family. The father died before John was born and two years later his mother married again. John was brought up with great care and tenderness. His later education was of the best character. He was a leader of his class as a scholar and an athlete. To his mother and intimates he displayed an intense selfishness, putting his interests and desires above all others, and had no consideration of the pain and distress of others. He was cruel in his conduct to any one who was in his way to the achievement of any purpose or desire. He finally became a lawyer and was thoroughly unscrupulous in

money matters. Although not miserly or avaricious, as a politician he was without honor or pride of character and would stoop to anything to accomplish his purpose. He married a rich woman and soon after swindled his father-in-law and possessed himself of a large property. Then he drank and began to live a fast life, had a mistress, attended horse races. Wherever he went he swindled and falsified and was feared by every one who had any dealings with him. He went into stock gambling and was swindled and swindled others. To his wife and children he was cruel and violent in his conduct. After a period of excessive use of spirits, he killed his wife and made no effort to conceal it, or run away. On the trial his schemes for deception and fraud were revealed to the astonishment of every one. Truthfulness, honor, duty, and all the qualities which go to make character were absent. He was convicted, but the sentence was commuted to a life imprisonment. In this case moral idiocy was inherited. The higher part of the brain was undeveloped and beyond the reach of culture and education. Without culture he would have early sunk to a low tramp criminal and burglar, and been a pauper degenerate, dying early. With culture he became a higher grade of criminal, and yet he was unable to appreciate ethical truth or moral relations. He was insane from birth; alcohol intensified and developed this condition. The insanity was of the higher ethical brain, and concealed except to those who knew him intimately.

Case 2.—The second case came from a good family and was normal in all his relations to others. Was truthful, honest, and seemed generous and very kind. After a severe attack of typhoid fever, in which he was given large quantities of spirits, he began to use alcohol daily. His father died and left him in charge of a large business interest. His character changed. His regard for his word was lost. He was suspicious of his mother and brothers, and took money out of the business and concealed it. He left his home for a hotel, and when drinking excessively, wrote violent scandalous letters to his family and employees. He associated with low women, but treated them harshly, refused to give them money, and was constantly in trouble. No public exposure disturbed him. He was frequently in court for petty swindles and refused to pay unless forced to. His business declined and was finally taken out of his hands, and he became a low blackmailer and beggar, drinking at all times and places. He was examined for lunacy and decided to be sane. No symptoms of insanity were found, nothing but wilfulness and vicious cunning, was the opinion of Philadelphia experts. Finally he was convicted as an accessory to murder and incendiarism, and sent to prison for life. This was clearly moral insanity acquired. His family and early history showed no trace of defective consciousness or moral weakness. His parents were temperate, moral people, church members above all suspicion. In his early life he attended church and Sunday school, and was a lovable, attractive character. He began his business career with his father, and seemed in every way most honorable and honest. He displayed excellent judgment and was intrusted with large business interests which he faithfully executed. During the illness from typhoid his father died, and on his recovery he was put in charge of the business. A total change of character which followed his recovery might have been due to the spirits given, or the injury of some local center from the fever. At all events, the use of alcohol intensified and fixed this condition. In both of these a great deal of mental vigor and superficial sanity was associated with this low moral brain force. The experts could find no impairment of his reasoning and memory, and concluded his conduct was simply vicious.

In the first case immoralities and dishonesties of conduct were judged from the same point of view. To these experts, failures to observe the relations of right and wrong, duty and obligation, had no physical basis, and were mere psychic temporary lapses. The use of alcohol was accountable for this and as this could be stopped any moment, it was a condition which the person could control at will. Fortunately such views are but the survival of theories of long ago. The central point I wish to emphasize is that moral insanity follows all use of alcohol, and is present in all inebriates to a greater or less degree. This condition is inherited and acquired, and exists to a far greater extent than would be supposed. There are many excellent men who use spirits not to a great excess, who are sufferers from disease. The constant beer and spirit drinker will be found to present the

most numerous examples. This field of study will furnish defects and degenerations, which follow the same uniform laws as other more apparent lesions.

SOME MEDICO-LEGAL ASPECTS OF SENILE DEMENTIA.

Presented to the Section on Neurology and Medical Jurisprudence at the Forty-ninth Annual Meeting of the American Medical Association, held at Denver, Colo., June 7-10, 1898.

BY WILLIAM B. FLETCHER, M.D.

INDIANAPOLIS, IND.

Perhaps the most marked feature in the relations of Law and Medicine which has become prominent within the last twenty-five years, is the tendency to "break wills," or contest them upon the ground of mental unsoundness; said mental unsoundness being usually attributed to the advanced age of the testator which the medical expert—being compelled to give a name—denominates "Senile Dementia."

It is not likely there are more old persons making wills, or that senile dementia is on the increase, and our query is: Why has litigation on this ground become more frequent than it was a half century ago? As our laws pertaining to wills have not changed, and as the disease—so-called senile dementia—has not changed, why is that about nine in ten wills made by wealthy persons are subject to litigation, and the wealth earned by the testator, which was as much his own as his watch or his jack-knife, is diverted from the channel indicated in his last request, into the pockets of the attorneys, primarily, and, occasionally—some of it—to the account of his unworthy and remote relations?

From careful observation extending over thirty-six years, I am of the opinion that the change referred to is largely due to a degeneration in the character of the Bar, and a decided weakness in the character of the Bench; attorneys who instigate litigation, and ignorant judges who sum up the evidence without knowledge and deliver weak opinions. Then, we have another cause: Our form of government; our system of education; and lack of that religious and moral training which teaches filial respect, gratitude and love for parents and benefactors.

Still another reason for breaking wills is the inadequacy of the statutory laws in most, if not all, of our States, to protect the wishes of the testator, and that the question of mental unsoundness is submitted to a jury of men totally ignorant of the whole subject of mental phenomena either in health or disease; and their knowledge of the case presented to them can only be gained through the tortured and tortuous examination and cross-examination of most ignorant men, women and children who are called as witnesses; and then, to complicate the matter, there are the lawyers for the prosecution and defense, who have gained a hurried something of senile dementia from some text-book—usually written by one not a professional alienist—and have a shallow knowledge of "will-making power" gleaned from theoretical essays, or works on medical jurisprudence written by a lawyer. All these causes are in constant action, and combined, produce those astonishing and unjust verdicts of "mental unsoundness" which are so commonly returned by juries in "will cases," and which are so encouraging to all the relations of a testator to the third and fourth generation. Then there is the judge—the thirteenth jurymen—ready to estimate

the value of the evidence, and also to give opinions and rulings. And yet, for a judge to translate, so to speak, the evidence in a case of insanity of any form, would require a knowledge of anatomy and physiology from the moment of conception to the period when the will was made, or the crime committed.

So much for the legal side of my subject, for the medical side cuts but a small figure. There are two kinds of medical experts. The first and largest class are professional experts. I mean those who will take a fee and appear before the jury for either the prosecution or defence—whichever will pay the most—as expert witnesses, in cases involving the most intricate knowledge of the chemistry of poisons, in surgery of all kinds, obstetrics, mental and nervous diseases. And there are experts well qualified, who are honest, but who are hoodwinked by the attorneys on either side to consent to a condition presented to them in a hypothetical case. Now, unfortunately, attorneys are not sworn to tell "the truth, the whole truth, and nothing but the truth," and the expert is employed according to his expressed opinion. The methods employed may be strictly legal in form, but the introduction of witnesses of fact, and of medical witnesses who are not alienists by profession, and of expert witnesses, almost forbids an appreciation of the truth as to the testamentary ability of the testator. No matter how great their ability, their value to the jury as a means of determining the mental condition of the testator is absolutely nothing more than the confusion of tongues in Babel.

The expert witness is not allowed to form an opinion from the evidence given by the witnesses, and thus explain to the judge and jury the value of the symptoms for or against the testator's mental soundness; but the expert witness must listen to a hypothetical case, yea, not one hypothetical case, but two, and from these hypothetical cases he must form and give a direct opinion as to the testator's mental condition. Now when we consider the fact that the attorneys are but playing a game of hazard, as much as a professional gambler does in a game of "draw poker," we can see how absolutely valueless the expert testimony may be made. The experts for the prosecution and those for the defense are pitted against each other as cocks in a cock-main—an expert acid and an expert alkali neutralizing each other.

I give as an example of legal logic, and how the medical expert is handled and compelled to swear falsely, the following: After the direct examination by the prosecution the expert is handed over to the defense. After again answering various unimportant questions as to former history, etc., the defense begins: "You have sworn that the animal in question that ate the cabbage was a rabbit. Now we wish you to listen to a hypothetical case: 'An animal was found eating the grocer's cabbage; this animal was of white skin with black spots; its hind quarters are slightly higher than its fore quarters; in movement it either runs, walks, or leaps; it has two eyes, and two ears, rather long, slightly pendent. It is predatory in its habits and a ruminative animal; it devours clover, grass, cabbage, etc.' Now, Doctor, with these facts as presented in our hypothetical case, is not this animal a goat? Answer my question." "Well, it might be either," answers the expert. Then the defense howls, appeals to the judge in a heated little speech for the benefit of the jury, and shows that the witness is either stubborn, or so ignorant that he does not know

a rabbit from a goat. Then the expert is finally pinned down to "no" or "yes," and he has to swear that which he knows to have been a rabbit was a goat. Then, when the defense gets its case on to the expert for the prosecution, said expert acknowledges that a goat is a rabbit, and the paid experts are arrayed against one another like champion football players, but the result is usually without effect upon the ignorant jury, or upon the judge.

The difficulty in the matter, when senile dementia or incapacity is made the basis of a suit, rests in the misapprehension that senility is insanity, whereas it is but a condition wherein the mind of aged persons no longer records new ideas, and has forgotten many old ones. It is a change, physiologic in character, that would come to every human being should the vitality of the heart and assimilation of nutriment continue long enough. The physical and mental activities are retarded and limited, but the memories stored up in the mind's great granary are rarely destroyed. An apple may have a speck of decay, and yet have much perfect and palatable fruit.

Bachal's description of old age shows a condition where life's beautiful sunset is pointed at by unprincipled lawyers and avaricious heirs as a black and bursting storm-cloud of disease: "Seated near the fire, and concentrated within himself, a stranger to everything without him, he passes his days there, deprived of desire, of passion and sensation. Speaking little because he is determined by nothing to break his silence, yet happy in feeling he still exists when almost every other sentiment is gone." To the physiologist it means diminished blood supply through an atrophied brain and changed qualities of blood through imperfect nutrition. The quality of the blood which is required for renewed mental activity is yet rich enough in vital principle to brush the dust from the pictured memories within the brain cells. This is senility. To entirely wipe out the images and thoughts etched upon the tablets of the minds of the aged is senile dementia. Now, there is a period where the transition is so slow from the former to the latter that it is extremely difficult for the laity, the judiciary, or even medical men who are not alienists, to determine the mental capacity of the aged subject. I would suggest and assert that where an individual owns property which he has acquired by his own efforts, and is able to describe that property, and knows to whom he wishes to convey it, that person, no matter what other mental deficiencies may exist, is of sufficiently sound mind to devise and will such property to whomsoever he may desire.

The gradual failure of the special senses by which all knowledge has been obtained deceives the unprofessional observer; the defective vision, the deafness usually associated with old age, disable the individual from participating in the social life about him, and with the fading brilliancy of the eye, the arcus senilis, and relaxed and atrophied lower jaw, give to the individual a peculiar stupid and demented expression, yet such person, properly addressed, will display that he has not yet ceased to think with some degree of accuracy and vigor. "The latter fact," says Ray, "will be known only to his intimate friends, while his defects are noted by common and occasional observers, who are always ready to decide upon a person's mental capacity from an occasional glimpse of his manner, or a few remarks upon most ordinary topics." Every physician knows that there are many old per-

sons who display lack of memory; many miscall names and do not recognize at all times—perhaps from imperfect vision—persons whom they have long known, yet, when the subject of property is touched upon, or their business interests mentioned, they understand perfectly well, and converse upon business and family matters with perfect understanding.

One of the greatest evils of our system of dealing with will contests, where the allegation is that of senile dementia, is that the trial is before a jury who know that the expert testimony upon both sides is paid for, and that the evidence given by experts is based upon hypothetical cases, and even a very ignorant jury would note the great discrepancy between the wily lawyers' hypothesis and the observed facts as related by the most ordinary witnesses. It is astonishing to note with what perfect ease the most stupid, ordinary, ignorant man, woman or child can calmly diagnose these cases which would puzzle the most proficient scholar in psychiatry, and by their testimony put the most expert alienist to shame before the jury. In a recent trial in Indiana, conducted by the most prominent attorneys in America, a will was thrown out upon the jury finding the old man who dictated it was of unsound mind. The following, in brief, is a sample of the evidence:

Witness (a negro barber) says "Mr. X. went to sleep while being shaved; when roused up looked kind of wild and confused."

Attorney—"Do you believe Mr. X. was of sound or unsound mind?"

Witness—"Unsound."

Newspaper boy—"Have seen Mr. X. often: sell him papers; he had tobacco spit in the corner of his mouth; looks like he don't know nothin'."

Attorney—"Do you think him of sound or unsound mind?"

Witness—"Unsound."

A farmer's testimony was that when the testator visited him he put his horse with others in a stall, and when he, the testator, was going away, he went into the wrong stall and put the harness upon the wrong horse.

Attorney—"Do you believe Mr. X. was of sound or unsound mind?"

Witness—"Unsound"—notwithstanding that the stable was dark and the testator could see, at best, but imperfectly.

A physician noticed Mr. X. at the postoffice: his trousers were not closed. "I whispered the fact to him, but he went on without correcting the impropriety." (X. was deaf as a post.)

Attorney—"Do you consider the man of sound or unsound mind?" "Witness—"Of unsound mind."

It was proven that the testator frequently forgot the names of persons; lost his locality at times; repeated the same things over. It was also proven that up to the time of making his will he kept accurate written account of all his business and financial transactions, and wrote most sensible and affectionate letters to his children and grandchildren—those children who, although left in affluence, rushed into court to put the stamp of insanity upon him ere the grass was grown over his grave. Thus, through the ignorance of the "thirteenth member of the jury," most ignorant witnesses were permitted to give expert testimony; were boldly encouraged to pronounce upon the physical condition and mental capacity of a person they hardly knew.

There is no standard by which mental capacity can be measured by the courts, and judges take to themselves the grave responsibility of deciding questions upon which they are as ignorant as they are adverse to one another. So uncertain are the judges, that they command neither the respect nor the confidence of the people, and are therefore shorn of the moral force and influence that properly appertain to judgments of courts.

The following will illustrate the views of a few eminent jurists upon the general subject of insanity:

"General insanity would necessarily preclude a trial, as a person in that condition can make no defense whatever."—Beardley, C. J.

"That you are of unsound mind I believe, but that is no reason why you should not be punished as an example to others."—Bramwell, B.

"To execute an insane person is against law, and of extreme inhumanity and cruelty, and can be no warning to others."—Sir E. Coke.

"To relieve from responsibility, insanity must be absolute; a man must know no more than an infant, a brute, or wild beast."—Tracy, J.

"Absolute insanity not necessary; if the prisoner was insane with reference to the crime charged, it is sufficient."—Beardley, C. J.

"It must be clearly shown that the accused did not know right from wrong. Partial insanity no bar to responsibility."—English Judges in Conference.

"The preceding opinion designated 'exquisitely inhumane' and absurdly impracticable."—Ladd, J.

"The test lies in the word 'power.' Had the accused power to know right from wrong, and had he power to adhere to the former and avoid the latter?"—Brewster, J.

"The law does not recognize 'uncontrollable impulse' if the prisoner knew right from wrong."—Alderson, B.

"There is an uncontrollable impulse, or irresistible inclination to kill, which, when proved, relieves from responsibility."—Gibson, C. J.

"If he knew that he was committing an act against God and nature, he is responsible."—Lord Lyndhurst.

"If the person acted under uncontrollable impulse, notwithstanding his knowledge, the act was not his act; hence he was not responsible."—Shaw, C. J.

"Moral insanity affirmed to be held a good defense by all enlightened jurists."—Robertson, J.

"Moral insanity denied as being a good defense, and the opinion that it was, declared to be most startling, irresponsible and dangerous doctrine, unknown to the courts of last resort in either Britain or this country."—Williams, C. J.

"If he did not know that the act he was doing was wrong, he is not responsible."—Tindal, C. J.

"If he knew that the act was wrong at the time he committed the deed, he is responsible."—Parke, B.

"The defense must prove absolute alienation beyond all doubt; such insanity as would prevent the accused from knowing that murder was a crime against the laws of God and nature, and that there was no other proof of insanity which would excuse murder or any other crime."—Sir James Mansfield.

"An insane man can not commit a crime. If there is a doubt of the insanity, how can the jury say a sane man committed the crime? A reasonable doubt as to insanity should avail as much as a doubt of any matter of fact."—Crawford, J.

"The onus of proving insanity is on the accused, and if left in doubt, the jury should convict."—Rolph, B.

"The onus of proof of insanity, as well as of guilt, rests on the State after the presumption of sanity has been removed by the defense."—Cooley, C. J.

"The proof of insanity to acquit should be as strong as the proof of guilt to convict."—Hornblower, C. J.

"If the jury entertain a reasonable doubt of insanity, they ought to acquit."—Doe, J.

"A preponderance of evidence in favor of insanity should acquit."—Shaw, C. J.

"Whether there is such a mental disease (dipsomania) is a matter of science and fact, not of law."—Smith, C. J.

"If he knew that the act was a crime forbidden by the law, he was responsible."—Lord Brougham.

"There are no legal tests of insanity. When the judge gives a legal test of insanity, he either testifies to a question of fact, or the expert witness has testified to a question of law. Thus the law is brought into conflict with itself."—Doe, J.

"The introduction of medical opinions and theories in the subject of insanity has proceeded upon the vicious principle of considering insanity a disease."—Lord Chancellor Westbury.

"Judges and lawyers, profoundly ignorant of insanity, have invaded the province of medical experts—the province of those who know all that is known on the subject—and for legal tests use exploded obsolete medical theories."—Doe, J.

"Ordinary men of the world are just as competent as witnesses as medical experts in insanity cases."—Bramwell, B.

"Medical experts are infinitely better qualified to judge of insanity than are courts or lawyers."—Ladd, J.

"Expert testimony not only of no value, but worse than that."—Davis, J.

"Expert testimony of great weight, and deserves the respectful consideration of the jury as competent evidence."—Shaw, C. J.

"The whole difficulty is that courts have undertaken to declare that to be a law which is a matter of fact. All symptoms and all tests of mental disease are purely matters of fact for the jury, and not matters of law for the judge."—Doe, J.

The constantly increasing litigation in America when questions of sanity and insanity are involved, demands some change in method and in law. Maudsley says: "It is notorious that the acquittal or conviction of a prisoner when insanity is alleged, is a matter of chance. Were the issue to be decided by tossing up a shilling instead of by the grave procedure of a trial in court, it could hardly be more uncertain." A celebrated British jurist says: "Acquittal on the plea of insanity is a mere matter of accident."

In one simple change of law much time and expensive litigation could be saved: 1, that the judge may only call upon experts to aid in translating, as it were, the evidence as given by the witnesses; 2, none but practical alienists should be called as experts in insanity cases. The general practitioner can not be an expert in insanity any more than a mechanical engineer could be an expert in the construction of a watch. The experts called by the court should hear all the evidence given, and not hypothetical cases of either side. Experts should be paid by the State or county, and not be allowed to take fees from either the prosecution or the defense.

When we have arrived, as we will in time, at that period of enlightenment, there will be less tendency to useless and unjust litigation; a man's property may be conveyed as he may devise; guilty persons will not be acquitted and innocent persons hanged in the sacred name of Justice.

SOME EXPERIMENTS IN URIC ACID—UREA.

EXCRETION BY THE KIDNEYS IN AN INDIVIDUAL UPON A MILK DIET, AND IN A CASE OF RECURRENT MELANCHOLY.

Presented to the Section on Neurology and Medical Jurisprudence at the Forty-ninth Annual Meeting of the American Medical Association, held at Denver, Colo., June 7-10, 1898.

BY F. SAVARY PEARCE, M.D.

INSTRUCTOR IN PHYSICAL DIAGNOSIS, UNIVERSITY OF PENNSYLVANIA; FELLOW OF THE COLLEGE OF PHYSICIANS. PHILADELPHIA.

I. MILK DIET.

Before the Section on General Medicine at the semi-centennial meeting of the ASSOCIATION the writer presented a study of "The Role of Uric Acid in Neurasthenia and Allied States,"¹ and drew the conclusions from the investigation that uric acid and its congeners must be potent causes in many cases of neurasthenia and other like nervous disorders, or must again cause aggravation of essential cases. Since that time further experiments as to the knowledge

¹ Virginia Medical Semi-Monthly, June 25, 1897; Medical and Surgical Reporter, March 31, 1898.

needed of internal metabolism and the significance of the amount of uric acid excretion to such bodily disturbance have been carried out; and, as first suggested in the paper quoted, the quantitative determination of uric acid on a milk diet has been sought for.

Dr. S. Weir Mitchell kindly selected a private case of exaggerated subconscious-self (hysteria) and of mild functional nerve tire at the Infirmary of Nervous Diseases for my urinalyses. This woman we feel was but little away from physiologic functionation, her malady being largely loss of will power, of idiopathic etiology. This is mentioned so as to not be misleading and to thus assume very probably about a normal secretion and excretion of an average individual, which is the desideratum. Having her under control in a hospital carried out the ideal conditions for watching and testing carefully the effects of milk diet on uric acid excretion in health.

Mrs. F. B., age 40 years. There is a negative family history. Patient has always been physically pretty healthy, but very nervous. When young was subject to causeless, painless and bloodless attacks of vomiting. No rumination. Menstruation first began at 13 years, is regular; lasting about one and a half days; scanty, but not painful. As further evidence of her essential nerve weakness, we may mention neuralgic attacks at 33 years and of causeless irritable bladder, the urine being found normal. No reason can be determined for her not ever being pregnant. Her generative organs are normal.

Hysterical manifestations in an exaggerated form followed business cares and the nursing of patient's father and mother, some seventeen months before the time she came under treatment, Nov. 11, 1897. The vomiting attacks of childhood recurred and became a "habit." She ejected much mucus—never food. Sudden hysterical gastrectasia and meteorism, with final abdominal contraction and sequent gushing of gas from the mouth ensued; occurring daily at exactly 4 P. M.—a mental habit—for two weeks before she came under treatment. She also then had marked subjective and objective vertigo, although her hearing and ears were pronounced normal. There were hysterical syncopal attacks, and daily nervous chills, attacks of transient amblyopia, intense frontal headache and at night frightful dreams, with jerking of head to the right, the consciousness always being preserved, however. Has not walked alone these seventeen months from supposed hip disease—also a hysterical vagary. We examined her very carefully and as to the secretions, but could find no physical or chemic alteration in any organ, excretive or secretive. Her appetite was very good, and after the thorough régime of the full "rest" treatment, became ravenous, so that she had discomfort after meals, and the ingesta was therefore lessened. Her tongue was large, clean, flabby, tooth-indented. There was no abdominal distress, but slight pressure tenderness on palpation over right upper quadrant of abdomen, due to the gastric distention noted. On being put to bed our patient's weight was 134 pounds, her temperature was 98 degrees F., respiration 20 and pulse 92, rhythmic and compressible. She was at first placed on the regular "house" diet—a cereal for breakfast, with the addition of four "meat balls" daily and Nestle's food 3iv in the morning on waking. Liquid malt 3ii was administered twice a day, and besides the usual general massage and faradism daily, phosphate of soda 3ss before meals and an occasional dose of spirits chloroform, gtt xv,

acted well as laxative and carminative: while the useful pil. sumbul comp., t. i. d., was the tonic therapeutics in the case. Fl. ext. cascara sag., gtt xx, at night, followed by a warm water enema at 10 A.M. proved of value when constipation was annoying. Her temperature was usually slightly elevated after massage.

With this outline the uric acid excretion remained normal up to Nov. 27, 1897, when she was placed upon a skim-milk diet; at first 3iv every two hours, gradually increased up to 3viii every two hours, when a dram of lime water was added to assist digestion; then the amount of milk was pushed to 3xii every two hours in the waking day. Some "fullness" in nape of neck was relieved by application of an ice bag daily, usually toward the evening hours. Isolation being insisted upon, we thus had, with Swedish movements added, an ideal rest with natural metabolism in an apparently healthy body, assisted by the passive exercise and absence in it of loss of nerve energy.

At the end of a fortnight the woman was gradually gotten up, at first fifteen minutes twice daily and increased five minutes at each daily sitting, as there was no necessity for prolonged rest in so actively hysterical a case, where true nerve exhaustion played so little a rôle. Dr. Thomson could find no adequate cause for headache in the eyes, and its irregular recurrence did not lead us to suppose it of metabolic origin. The following table (No. 1) gives the results of my urinalyses during the milk period and after, from Dec. 4 to Dec. 23, 1897, beginning after the woman had been upon milk alone for a week. The urea was also estimated upon a number of occasions. The amount of milk administered reached at its acme one hundred and twenty ounces, proving the normal metabolism of the system; for, too, there was at no time oxalates to make suspicious such suboxidation.

The method employed for quantitative uric acid determination was that of Heintz, previously detailed in my paper already quoted, and therefore (worked under similar conditions of examining the specimen at once) there can be but little fallacy in the findings.²

Taking the normal excretion of urea as 2.8 per cent. and of uric acid as .05 per cent. (i. e. 2.8 gm. urea in 24 hours, and 6 gm. uric acid in 24 hours—and 8 gm. NaCl in 24 hours) it is to be noted at the end of the week of milk diet the urea had fallen to 1.4 per cent. while the uric acid had lessened to .04 per cent., the amount of urine excreted varying daily from 20 to 30 cm. (2630 c.c.) as shown in Table I. The lessening of pigment was a notable point; also the reduction in all solids as shown by the sp. gr. gradually lessening from 1020 at first to 1012 at end of first week on the milk diet, to 1010 at the end of a fortnight. Now the urea had become reduced to 1.3 per cent. and uric acid to .03 per cent., so that very few crystals could be detected without centrifugation. The urine had now become very limpid, of a light greenish color, and contained practically no deposit, and reaching by the eighteenth day of milk diet without vacillation the lowest ebb in both urea (1.2 per cent.) and uric acid (.019 per cent.). The uric acid continued to recede after eggs had now been added to the diet for 24 hours (to .016 per cent.); the urea promptly rising in the same time, however, to 1.4 per

² In a private communication from Dr. Chas. E. Simon, the kind suggestion to adopt the Hopkins method, "with the modification that you decompose your ammonium urate with a decinormal solution of HCl and retitrate the excess with NaOH, using dimethyl-acido-azo-benzol as an indicator, 1 c.c., corresponding to 0.0168 gm. of uric acid," will be used in future work.

cent. This we feel rules an excess of uric acid in this case out of court—a normal condition of body.

House (meat) diet was ordered on the twenty-second day, and the urea, which had then risen to 2 per cent., became less (1.6 per cent.), while the uric acid, which had the day before begun to rise, now took on more active production and elimination, reaching .03 per cent. on the twenty-second and .034 per cent. on the twenty-third day of experimentation, the urea coming slowly up to 1.8 per cent.; and on the twenty-fourth day urea reached the 2 per cent. mark, uric acid being .036 per cent. On the twenty-fifth day the urea remained at 2 per cent., while the uric acid tide had risen to 4 per cent., and on the twenty-sixth day the uric acid was recorded .046 per cent. (about normal), while the urea was lacking 8 per cent. of normal.

This see-sawing in the relative proportion of urea and uric acid, while showing on the whole the tendency to lessening of both when proteids are cut off or bodily tissues are suboxidized, yet, as held in my previous studies, shows clearly enough that the ratio of urea to uric acid is not held at a fixed proportion, but that if one is *more* the other is apt to be *less*, no doubt due to the degree of oxidation in the process. Recent studies of urine have further legitimately proven that where there is much disturbance of metabolism in a given case, besides this urea-uric acid disproportion, oxalate crystals are more in evidence.

Now in the past year, since we have gotten a reliable quantitative test for indican,³ we may yet hope for some reliable quantitative proportion test of oxalates and other by-products to uric acid; and that the therapeutic value of such understanding may further on in physiologic chemistry help our treatment of the dread uric acid diathesis.

5. Urea at the end of twenty-second day is 1.6 per cent., uric acid is .03 per cent.; diet again increased.

6. Urea at the end of twenty-sixth day back to 2 per cent., little less than normal; uric acid to .046 per cent., slightly less than normal. The patient's weight on Nov. 13, 1897, was 134 pounds, by the 27th excess of fat was massaged away to 132 pounds. Eleven days on a milk diet brought her up to 136½ pounds, and on December 25 it was 144½ pounds, on Jan. 8, 1898, 154 pounds, a gain of twenty-one and one-half pounds in forty-two days.

7. Urine progressively decreased in amount when patient was taken off milk diet largely and solid food substituted. (Proteid food produces about half uric acid formed perhaps, the rest probably coming from body by oxidation; see No. 10.)

8. Specific gravity lowered in proportion to increase in the amount of urine excreted.

9. Color of urine lessened in proportion to increase in the amount of urine excreted.

10. It is here positively established that uric acid in the urine is reduced to a minimum on a milk diet (about one half the normal).

11. Trace of *indican detected on twentieth, twenty-first, twenty-second and twenty-third days after solid food was largely added (fermentation).

IN SHORT RECURRENT MELANCHOLY.

The following table (No. 2) is the detailed record of a case of irregular mental depression of short duration in the case of a man in otherwise excellent health, and whose case is detailed by Dr. Weir Mitchell,⁴ to which very singularly interesting clinical record the reader is referred. The conclusions we reached from the examination of this middle-aged man's urine have been stated by Dr. Mitchell in his book, and I am again indebted to that gentlemen for permission to publish first here the details in tabular form, which are somewhat in accord with work done later by Dr. Cleon M. Hibbard,⁵ and of the pioneer in uric acid studies, Haig, who refers to the same conditions.⁶

Our own experiments in states of mental depression are confined to the critical analyses in this one case

TABLE 1.—URIC ACID FINDINGS (MILK DIET).

Date.	Amount, twenty-four hours.	Amount taken in ounces.	Specific gravity.	Color and sediment.	Urea, percentage.	Uric acid, grams to per cent.	Notes.
Dec. 4, 1897.	83 oz. or 2490 c.c.	8	1012	Light straw	1.4	.04	End of first week on milk, 4 ounces (with 1 dram aq. calcis) every two hours until 12 ounces milk every two hours taken (120 ounces.)
Dec. 5, 1897.	88 oz. or 2540 c.c.	8	1011	Light greenish.039	
Dec. 6, 1897.	82 oz. or 2460 c.c.	8	1010	Light greenish, no pigment.038	
Dec. 7, 1897.	83 oz. or 2490 c.c.	8	1010	Light greenish, no pigment.034	
Dec. 8, 1897.	86 oz. or 2580 c.c.	8	1010	Light greenish, no pigment.032	
Dec. 9, 1897.	80 oz. or 2400 c.c.	8	1009	Light greenish, no pigment.032	Weight, 136 pounds end of second week on milk.
Dec. 10, 1897.	82 oz. or 2460 c.c.	8	1010	Light greenish, no pigment.031	
Dec. 11, 1897.	84 oz. or 2520 c.c.	8	1011	Light greenish, no pigment.	1.3	.03+	
Dec. 12, 1897.	85 oz. or 2550 c.c.	8	1011	Light greenish, no pigment.029	
Dec. 13, 1897.	82 oz. or 2460 c.c.	8	1012	Light greenish, no pigment.03+	
Dec. 14, 1897.	80 oz. or 2400 c.c.	8	1012	Light greenish, no pigment.	1.2	.028	Menstruation regular.
Dec. 15, 1897.	70 oz. or 2100 c.c.	8	1014	Light greenish, no pigment.019	
Dec. 16, 1897.	70 oz. or 2100 c.c.	8	1013	Light straw	1.4	.016	Diet (eggs, soups) increased eighteenth day.
Dec. 17, 1897.	65 oz. or 1950 c.c.	8	1014	Light straw018	
Dec. 18, 1897.	68 oz. or 2040 c.c.	8	1016	Darker pigment.	1.2	.023	No medicine except occasional dose of trional or bromid for insomnia spts. chloroformi for acidity of stomach twenty-sixth day.
Dec. 19, 1897.	69 oz. or 2070 c.c.	8	1020	Natural straw color.	1.6	.03	
Dec. 20, 1897.	69 oz. or 2070 c.c.	8	1020	Natural straw color.	1.8	.034	
Dec. 21, 1897.	68 oz. or 2040 c.c.	8	1021	Natural straw color.	1.2	.036	
Dec. 22, 1897.	64 oz. or 1920 c.c.	8	1021+	Natural straw color.	1.2	.04	
Dec. 23, 1897.	60 oz. or 1800 c.c.	8	1023	High color, slight sediment, urates.	1.2	.046	

No albumin, glucose nor indican found, except a trace of indican on December 20.

POINTS IN CONCLUSION IN URINE FINDINGS IN MILK-DIET CASE.

1. Great increase of amount of urine in one week after, upon skim milk alone (up to 120 ounces in twenty-four hours), the patient passing twice the normal amount of limpid urine.

2. Urea at the end of first week goes down to one-half normal, uric acid to .04 per cent.

3. Urea at the end of second week goes down to 1.3 per cent. and uric acid to .03 per cent. Up to this time amount of urine remaining twice normal.

4. Urea at the end of eighteenth day is 1.4 per cent., uric acid .016 per cent., one-fifth of normal. Diet now increased.

³ A Method for the Quantitative Estimation of Indican and Indirubin in the Urine. H. Richardson, M.D. and E. L. Whitney, M.D. (JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION, April 16, 1898.)

of short but decided recurrences without other known cause, and where melancholy rather than true melancholia seems the better term to use, as suggested by Dr. Mitchell in this case, since the man is not unbalanced by the "cloud suddenly descending unawares

upon him," and yet making the *compos mentis* suffering the more acute.

This man has greatly improved since last year by regularly abstaining from excess of proteids, by care as to bodily chilling and by outdoor life on his ranch in Iowa. "Dull care" we hope may finally be driven away by super-oxidation and restored nutrition.

We hope in future studies to elaborate the suggestive steps indicated in this work, but feel today confident of almost as wide a horizon in the sphere of etiology of disease through perverted metabolism as in the domain of bacteriology. Many of the remote reasons for such disturbed metabolic action may perhaps never be determined, yet the results are becoming

TABLE II.—EXAMINATIONS OF MR. C. E. (RECURRENT MELANCHOLY).
Urine of twenty-four hours; 7 P.M. to 7 P.M.

Date.	Condition.	Amount.	Amount taken, ounces.	Sp. gr.	Color.	Urea; grams in 1 c.c.	Uric acid.	Blood.
Jan. 13, 1897.	Depressed ten hours	45 oz. or 1350 c.c.	8	1020	All clear straw; acid.	.026542 = 2.6%	10 ¹ / ₄ grs.	
Jan. 14, 1897.	Wt. patient, urine while much depressed	55 oz. or 1650 c.c.	8	1014		.024192 = 2.4%	10 ¹ / ₂ grs.; indican +	
Jan. 14, 1897.	Not depressed latter part of day	55 oz. or 1650 c.c.	8	1018		.025290 = 2.5%	100 mgm. in 200 c.c.; indican	
Jan. 15, 1897.	Well, unusually so during last 17 hrs.	37 oz. or 1110 c.c.	8	1022		.02688 = 2.6%	8 ¹ / ₄ grs.; indican	
Jan. 16, 1897.	Slept well; B. normal; pulse small, 74 to min.; T. 98.4° F.	45 oz. or 1350 c.c.	8	1020		.02474 = 2.4%	9 ³ / ₄ grs.; indican	
Jan. 17, 1897.	Reasonably well	42 oz. or 1260 c.c.	8	1018		.02688 = 2.6%	9 20 grs.; indican	7:30 P.M.; good spirits; r.b.c.
Jan. 18, 1897.	Very bright	55 oz. or 1650 c.c.	8	1020		.02688 = 2.6%	10 ¹ / ₂ grs.; no indican	4,200,000; H = 90; w. b. c.

* Patient's ever-changing mental state entailed frequent urinalyses on Jan. 20. No brickdust deposit, albumin or glucose in any of above.

ANALYSIS OF TABLE—QUANTITATIVE FINDINGS AS TO URIC ACID, UREA AND INDICAN IN THIRTEEN SPECIMENS.

1. Urine was saved for twenty-four hours.
2. Eight ounces of the amount used in tests.
3. Amounts passed in twenty four hours calculated as to proportion of uric acid and urea voided.
4. Specific gravity recorded.
5. Per cent. of urea given.
6. Grains of uric acid (11 normal for 1200 c.c.) voided in the entire amount of twenty-four hours' urine.
7. Indican tested as to color (with muriatic acid and sat. sol. chlorid of lime).
8. Albumin and glucose tested for in each case.
9. Patient was on ordinary "mixed" diet and in full activity. No medicine.
10. R. b. c., 4,200,000. No leucocytosis. H = 90 per cent.

CONCLUSIONS—URINE ANALYSIS, CASE OF RECURRENT MELANCHOLIA.

1. The specific gravity of the urine bore no relation to amount of urine voided.
2. The acidity of the urine was always marked.
3. Color of urine was higher when amount voided smaller.
4. There was no "brick dust" deposit of urates.
5. Average amount of urea voided in twenty-four hours equaled 2.5 per cent.
6. The normal (urea) being 2.7 to 3 per cent., this reduction can not be positively stated as abnormal, but the continuous subnormal amount with the fact that more than the average quantity of urine voided continuously would lead to the thought that suboxidation of proteids existed.
7. The lowest amounts of urea were recovered on the two occasions when the patient was much depressed mentally, viz., Jan. 14, 1897, 2.4 per cent. and Jan. 21, 1897, 2.4 per cent. In other examinations, recovered 2.5 and 2.6 per cent.
8. On corresponding dates, Jan. 14, 1897, uric acid equaled 10.5 grains, calculated for twenty four hours; Jan. 20, 1897, uric acid equaled 8 grains, calculated for twenty-four hours.
9. In the former (Jan. 14, 1897) 1650 c.c. voided in twenty-four hours, specific gravity 1014; in the latter (Jan. 20, 1897) only 990 c.c. voided in twenty four hours, specific gravity 1022.
10. Marked color reaction for indican was obtained in each of the two attacks of depression noted during the study. It was found in less amount in seven of the remaining eleven specimens recorded in the table.
11. The patient passed 55 ounces (1650 c.c.) on one day of his typic depression, the second day only passing 33 ounces (990 c.c.).
12. As both contained indican in large (color reaction) amounts, intestinal putrefaction may possibly be an important factor.
13. No albumin or glucose found in any specimen.
14. As to where the uric acid may be when not recovered in urine could possibly be told by difficult analysis of the blood at the time.

more manifest and we are grossly derelict of duty if we fail to search and apply the therapeutic measure for relief and cure. The actual "why" is not always possible to find out. An intelligent woman recently, on learning of the theory of the neuron, immediately put the trite question: "Why should the neurons have motion?"

THE PULSE: ITS DIAGNOSTIC AND PROGNOSTIC VALUE.

Read before the Orleans Parish, La., Medical Society, Sept. 24, 1898.
BY T. S. DABNEY, M.D.
NEW ORLEANS, LA.

The proper study of mankind is man.—Pope.
Have you a working pulse?—Shakespeare.

Mr. President and Gentlemen: In the mad scramble for novelties which seems to have seized our profession, as it did the ancient Athenians, you may be surprised at my presumption in asking your attention to so prosaic a subject as "The Pulse: Its Diagnostic and Prognostic Value."

This is the age of the infinitesimally small, and he who would spring, like Minerva, full grown into fame, must, like Pasteur, Koch, Sanarelli, Klebs, Loeffler, Eberth and Laveran, succeed in standing sponsor for some micro-organism. Failing that, you might yet seek the "bubble reputation" by investigations into the biology of certain of these lower forms of life, and like MacCallum and Opie of Johns Hopkins, succeed in catching the Halteridium of Labbe in his amorous advances. These observers having shown that the passive granular form of this hematazoon is the female, and the lusty, aggressive hyaline form the male, is but to open the way for a more thorough study of their family relations.

Pardon me for this digression, but I felt some apology due you for occupying your time with the pulse of man himself instead of that of some schizomyces. Without underestimating the labors of those toilers in the hitherto untrodden fields of bacteriology, you will yet excuse me for not believing that man is of the bacillus, by the bacillus and for the bacillus.

The physicians in the olden times gave much careful attention to the pulse, and the amount of information to be gained in its study is astounding. By the introduction of percussion by Anenbrugger in 1761, and auscultation by Lænnec in 1816, the interest in the study of the pulse, was decidedly lessened. This interest was further diminished by the introduction in 1861 by Marey, of the sphygmograph. The clinical thermometer, introduced somewhat later, dealt a death-blow to the painstaking study of the pulse. Every new study tends to force the old to the background. We must ever bear in mind that not all that is old is bad, nor all that is new good. Let us rather follow the noble advice given by St. Paul to the Thessalonians: "Prove all things; hold fast that which is good." Tried in the crucible of time the gold can be separated from the dross. I hold with Cicero that: "Not to know what happened before we were born is to remain always a child." I welcome every new discovery that renders diagnosis or prognosis more certain, and while fully appreciating the impetus given physical diagnosis by the introduction of means and methods of precision, yet I firmly believe in holding fast to all that is good and in profiting by the experience of those that preceded us.

The value of the study of the pulse can not be overestimated. The sphygmograph but records what the finger feels, and the more the finger is educated the more it feels. The tracing of the sphygmograph is, as it were, a photograph of the pulse, and like all photographs, lacks tone, expression and volume—the original must have been known to be appreciated. Without seriously considering the claims of the Arabs, Moors and Chinese—and their claims are many—we may state that Galen of Pergamos, Mysia, is the earliest authentic writer on the pulse, and he seems to have read it like an open book. I do not believe there is a more masterly and comprehensive treatise on this subject than that by him who won the double sobriquet of "Paradoxologus" (wonder-speaker), and "Paradoxopœus" (wonder-worker), in imperial Rome, where he became the physician to the emperors, Lucius Verus and Marcus Aurelius. To Galen, the pulse seemed to speak, and his prognosis, based upon it, often smacks of the marvelous. Though living in the second century, he was unquestionably a great physician, and to his close study of the pulse, much, if not most, of his reputation was due; for it is an indisputable fact that nothing adds more to a physician's fame than an accurate prognosis. Nothing strikes the human intellect with more awe than one's ability to read aright the portents of the taps of those "muffled drums (that) are beating funeral marches to the grave."

Strange as it may appear, Hippocrates seems to have paid as little attention to the value of the pulse as the majority of the teachers of physical diagnosis in our schools today. About all to be learned of the pulse in the average medical school, now-a-days, is to count it.

Galen named and accurately described thirty-six different varieties of the pulse. Just think of it! I can not do better than to reproduce his original table:

1. Long pulse; the artery strikes several or all of the fingers.
2. Short pulse; artery strikes only one or two fingers.
3. Wide pulse; artery distended.
4. Narrow pulse; artery contracted.
5. Elevated pulse; artery strikes forcibly and repels hand.
6. Low pulse; artery scarcely perceptible.
7. Big pulse; artery distended in width, length and elevation.

8. Small pulse; artery little distended according to these three diameters.

9. Quick.
10. Slow.
11. Frequent.
12. Rare.
13. Vehement or strong; artery strikes fingers forcibly.
14. Feeble or languishing; reverse of above.
15. Hard; the finger yields to the pulsation.
16. Soft; the pulsation yields to the compressing finger.
17. Full; the artery is full and resists the touch.
18. Empty; the artery disappears, yielding to the finger, possessing no solidity.
19. Equal.
20. Unequal.
21. Rat-tail; starts large and rapidly diminishes down to a point like a rat's tail.
22. The feeble rat-tail; one seeming to cease, or ceasing altogether.
23. The rat-tail that strikes more forcibly the two middle fingers, scarcely touching the first and last.
24. Intermittent.
25. Intercident.
26. Failing; stopping altogether.
27. Capricious; interrupted in the middle of its diastole, then finishing in quicker time than of its commencement.
28. Dicrotic; striking twice like a hammer rebounding from an anvil.
29. Wavy; rising gradually under the fingers.
30. Vermicular; like a worm.
31. Formicating; like an ant.
32. Trembling.
33. Palpitating.
34. Convulsive; artery tense like a cord.
35. Serrated; strikes fingers unequally, like a saw.
36. Ardent; artery rising and striking promptly and forcibly.

To take the pulse properly, the physician should be seated by the side of the patient, who should be in a sitting or recumbent posture, with arm extended and resting on some support. The physician should lightly place the four fingers of his right hand over the left radial artery of the patient, with his index finger nearest patient's hand; the little finger will thus be the first to receive the stroke. The pulse should always be taken at each wrist, for reasons to be given later. By so doing the presence of aneurysms can often be suspected, and frequently verified. Pressure should alternately be made and relaxed to determine the hardness or softness, force or feebleness, the largeness or smallness, the swiftness or slowness of the pulse. Again, other factors, such as the frequency, the rareness, the irregularity, the inequality, must be taken into account. A strong pulse is characterized by volume and vigor; a weak one by the reverse conditions. To the tyro, the number of pulsations to the minute, which can generally be counted accurately by means of a watch, is all-important; but valuable as this information often is, it is the least important of all other signs to the experienced clinician, who cares little whether the heart contracts seventy-five or a hundred times a minute. He is mainly interested in the dynamics of the viscus, rather than in the derangement of its running-gear. A few drops of digitalis, the fractional part of a grain of glonoin, a glass of beer, fright and the various neuroses, readily serve to affect the inhibitory or accelerator fibers of that "rope of mingled strands"—the vagus and the sympathetic system. Above all things, should the family physician be familiar with the pulses of his patients in health, for, as is well known, some families have abnormally slow and others fast pulses. According to Fothergill (*The Physiologic Factor in Diagnosis*), "a pulse of 40 or even less is not rare" (normally). All of us are familiar with patients whose pulses in health run from 90 to 100 and even higher. Then again, arrhythmia, cousin-

germain to the dilated ventricle, is normal in a number of persons whose hearts beat with regularity only under the stimulating effects of pyrexia. Again, we find intermittency—that sign so closely linked with muscular and structural decay, always alarming and frequently speaking in unmistakable tones of impending disaster—is often but a neurotic trick, or else it may be caused by any sudden shock, by excitement, by advancing years, or in the convalescence from severe illness. We should ever bear in mind that the pulse depends upon three things: the ventricular systole, the arterial walls and the state of the arterioles.

The antithesis in the state of the arterioles is beautifully shown in the pyrexias, and in the granular kidney. In the former the blood flows freely through relaxed arterioles, giving us the rapid pulse of half-distended and slack vessels. The accelerator fibers of the vagus or sympathetic being stimulated, the heart pumps vigorously to supply blood for the unfilled vessels. In the latter, the roots of the vagus being flooded the inhibitory strands of the vagus are excited and the heart's action slowed, and we have the ominous, cord-like pulse of high arterial tension. As a fast pulse does not necessarily imply mural decay nor pyrexia, so a slow one is not of necessity of grave import. That the slow pulse of yellow fever is not due to any specific bacillus nor its ptomaines, but rather to the toxic effect of an accumulation of the bile salts in the blood is clearly shown by the presence of the same symptom in ordinary cases of icterus. This fact is further accentuated by the coincidence of the appearance of colemia and the bradycardia and by their disappearance *pari passu*. It may, *en passant*, be stated (Louis' law) that the earlier the appearance of jaundice (pronounced) the graver the prognosis; commencing by or before the third day, death is almost certain; by the fifth day, death more probable than recovery; after seventh day, recovery almost assured. It will thus be seen that bile, like muscarin, first markedly slows the heart's action by powerfully irritating the inhibitory fibers of the vagus. If this irritation be carried too far the heart's action is slowed down until it ceases altogether. In such an event the patient will be found to be of a bronzed or mahogany tint, so marked is the cholemia. Accepting this as a fact the logical treatment readily suggests itself and the rationale of the large, high saline enemata is understood. However, the ordinary slow pulse of typhus icteroides, as you all know full well, is not of grave moment. The danger lies in the rising and not in the falling pulse ordinarily. To put it more scientifically, we have more to apprehend in this disease from the stimulating effect of some specific toxin upon the accelerator fibers of the sympathetic system than from the effect of bile upon the inhibitory centers of cerebro-spinal origin. It is hardly necessary, in this connection, to call your attention to the lack of correlation of pulse and temperature so pronounced in yellow fever; but it may not be amiss as a diagnostic point, to state that a falling pulse, taken in connection with a rising temperature in an acute febrile disease, is well nigh pathognomonic of yellow fever. The elder Faget called particular attention to this anomaly.

It is in pulmonary disease that the prognostic value of the pulse is invaluable. Be it phthisis or pneumonia, a rapid and steadily-increasing pulse-rate is ominous. In the early diagnosis of phthisis, I regard it as far more valuable than the clinical thermometer, though the value of that instrument can hardly be

overestimated. Often the rapid pulse will enable one to diagnose phthisis before the thermometer gives any evidence of pyrexia, and long before any physical signs are appreciable. A pulse running from 90 to 100 habitually, in a person of bad family history, demands your urgent attention, and you should not lose valuable time waiting for "cultures" to confirm your suspicions, but act promptly in giving your patient the benefit of the best dietetic, therapeutic and climatic treatment—treat the disease first, diagnose it afterward, and thereby avoid following the advice, seriously given to his class, of a distinguished pathologist of my acquaintance: "follow *all* their patients to the dead-house."

The fast pulse of nervousness can readily be differentiated. You should also bear in mind that tachycardia in old alcoholics, is the rule, and hence of no prognostic value. Moderate but habitual drinkers generally have an accelerated pulse-rate. All you gentlemen who have had occasion to make many examinations for life assurance—I think "assurance" the correct term—must have been struck with this peculiarity of the pulse of the ordinary man-around-town who habitually takes a stimulant with his lunch, and usually a cocktail before dinner, and a postcoital *pousse-café*.

The bradycardia of fatty degeneration of the heart is apparent rather than real, as many of the ventricular contractions are too feeble to propel the blood with sufficient force to be appreciated at the radial. The stethoscope will clear up the discrepancy. The slow pulse of the gouty heart, or rather the hypertrophied heart of chronic Bright's disease, is readily differentiated, as it is tense and cord-like and usually accompanied by large quantities of limpid urine of low specific gravity. However, in time, when fatty degeneration sets in, and the walls of the heart become weakened, the ventricles lose their force, and the urine becomes scanty and high-colored. When this stage is reached, the patient is on the down-grade, or as Fothergill tersely puts it: "An increasing bulk of urine tells that the case is at the stage of waxing hypertrophy; the fall in bulk tells that the hypertrophy is being undermined by a histolytic process." From a prognostic point of view, this symptom can not be too strongly insisted upon, for as Traube truly says, a high blood-pressure means a large bulk of urine, and conversely. The polyuria of hysteria, with its tight pulse, is but another proof of Traube's aphorism. The large quantity of limpid urine passed by the hysteric, robs the high arterial tension found in this class, of its significance. The pulse of failing hypertrophy is so characteristic and is fraught with such a hopeless prognosis that you will pardon my stating that whenever the pulse of a sufferer from chronic nephritis beats regularly for several strokes, quickly followed by several imperfect strokes, a slight halt, and then a full contraction, you may safely say that the curtain on the last act of the drama of life is about to be rung down.

The simple halt of the neurotic or the dyspeptic can never be mistaken for this grave sign, as it is never preceded by the imperfect strokes. However, in some dyspeptics the halt is so well marked as to be plainly and painfully remarked by the patients themselves. Much needless suffering has been caused this unfortunate class of patients by the hasty diagnosis of heart disease. I recall the case of a wealthy lady of this city, a great sufferer from atonic dyspepsia and this

form of abrupt halt, who, for years, was in constant dread of sudden death. In spite of my frequent assurances that her stomach and not her heart was the viscus affected, she could not quite believe that her former medical advisers were all wrong, and I alone right, for, "can I not feel my heart stop?" she would often say. During one of her trips north, I prevailed on her to consult that chief among diagnosticians, DaCosta. Since that time, ten years ago, she has learned that flatulence by pressure on the tendinous portion of the diaphragm can cause tumultuous action of the heart as well as complete intermittency.

Dr. Dehio of Dorpat claims that most cases of bradycardia are due to nutritional changes in the automatic nerve centers in the heart, dependent probably on local sclerosis of the branches of the coronary arteries leading to such centers. As shown by Dr. J. W. Ogle (London *Lancet*, February, 1898) in four cases reported by him to the London Pathological Society, the bradycardia was associated with thickening of the endocardium and fibrinous deposits mostly at the bases of the ventricles. The bradycardia of true angina pectoris is nearly always associated with sclerosis, calcification or ossification of the coronary arteries themselves, or else a similar condition at or near the aortic opening. This condition renders the prognosis very grave, and calls for promptness in lowering arterial tension, in toning up the cardiac musculature, and in anticipating cerebral ischemia. The prompt administration of such remedies as nitrite amyl, trinitrin and strychnia, with the continued use of the iodids, fulfil such requirements. All vasoconstrictors, such as ergot, digitalis and quinin, should be studiously avoided. Morphia should be given, *if at all*, with the greatest caution.

In this connection it might be well to call attention to the cardiac ganglia imbedded in the auricles. These ganglia are intimately connected with the sympathetic nervous system. They are purely sensory, and have no motor fibers. Romberg and His have demonstrated in the heart muscular transition fibers that pass directly from the auricles to the ventricles, and the rhythmic action of the heart is now believed to be entirely dependent upon the contraction of these muscular fibers, and is not due, as was generally held, to the cerebrospinal or sympathetic systems. The action of the heart is therefore automatic. Uremia is responsible for a considerable number of cases of bradycardia. These cases are markedly benefited by rest, a milk diet, warm baths and abundance of pure water. The great majority of cases of bradycardia are due to diseases of the cord and brain. In these cases the prognosis is hopeless. The prognosis in other cases depends upon the cause—toxemias, neuroses, reflex, and convalescence from various diseases, etc.

The cause, taken in connection with the dynamics of the heart, should enable you to prognosticate accurately. Given a slow pulse, accompanied, upon slight exertion, by vertigo from cerebral anemia, cyanosis and dyspnea, your prognosis must of necessity be grave; but, on the other hand, as long as the slow, strong beats of the heart supply all wants of brain and body, the prognosis is favorable. However, it can be stated broadly, that arrhythmia is usually of grave import. Occurring in children in connection with fever, it is strongly suggestive of tuberculous meningitis.

The unequal pulse always demands a guarded prog-

nosis, as it usually denotes an aneurysm involving the root of the subclavian artery, although it may be due to obliteration of the radial by injury or by some growth making pressure on the vessel. At other times it is purely neurotic.

It is beyond the scope of this paper to enter into details in reference to the many varieties of pulse and their significance. I have endeavored but to point the way and to remind all general practitioners of medicine that "the proper study of mankind is man," and the more thorough our study of man, the more competent and successful practitioners we will become. I would not dissuade any of the younger members of the profession from the alluring fields of bacteriology, for medicine is under lasting obligations to the careful students of the lower forms of life, but let us never forget that it is by the art and not by the science of medicine that we gain our reputation, and, incidentally, our livelihood. All can not be celebrated botanists, chemists, neurologists, bacteriologists and pathologists. Let us take unto ourselves the homely proverb, *ne sutor crepidam judicaret*. By availing ourselves of the labors of these men in special fields we will profit greatly; but our success as practising physicians, now, as formerly, will depend upon our close observation of all that concerns *homo humanus*.

Charles Darwin was astounded at the instantaneous and immense reputation his "Origin of Species" brought him. He tells us in his modest way that he had done nothing but *observe* closely; aye, there is the secret, he had *observed*, closely, accurately, scientifically, the minutest detail. As in natural history, so in medicine. How many of us have eyes, yet see not; ears, yet hear not? Shakespeare spoke truly when he said: "Most poor things point to rich ends." There are men in our calling who have studied so carefully the stomach of the mosquito that they are able to tell you all the reasons why the malarial hematozoon prefers that particular viscus of that particular dipter to that of its gregarines or coccidia. This is all very interesting and scientific, but we do not treat gastric catarrh of the mosquito. By close observation of the laws of health and disease, we all may become qualified to practice the art of medicine successfully. It is a well-known fact that the treatment of many diseases, notably pneumonia, tuberculosis, malaria and pertussis, has not been crowned with better results since the microscope has introduced to us the Lilliputian armies that cause their pathology; nor have the most successful practitioners been those best versed in the pure realms of science. The close observers have always, in every age, been the most successful physicians. With Oliver Wendell Holmes I say:

How blest is he who knows no meaner strife,
Than art's long struggle with the foes of life.

A CASE OF ADIPOSIS DOLOROSA.

Presented to the Section on Neurology and Medical Jurisprudence, at the Forty-ninth Annual Meeting of the American Medical Association, held at Denver, Colo., June 7-10, 1898.

BY AUGUSTUS A. ESHNER, M.D.,

PROFESSOR OF CLINICAL MEDICINE IN THE PHILADELPHIA POLYCLINIC;
PHYSICIAN TO THE PHILADELPHIA HOSPITAL, ETC.
PHILADELPHIA, PA.

In a paper read before the Philadelphia Neurological Society in 1891, Henry¹ reported the case of a married woman, 63 years old, in whom, at the age of

¹ Journal of Nervous and Mental Disease, March, 1891, p. 154.

49, somewhat circumscribed, painful, fatty swellings appeared successively in various parts of the body. The patient was an immoderate drinker and had had epileptiform convulsions frequently in infancy. Menstruation had begun at 11 and had ceased abruptly at 35. Sensibility was impaired in proportion to the deposition of fat. The case was described as one of *myxedematoid dystrophy*, and for the condition the designation *paratropy* was proposed. In a paper read before the American Neurological Association in 1888, Dercum² reported the case of a widow, 51 years old, in whom the arms began to enlarge at the age of 48 or 49 and were the seat of pain. Back, shoulders, arms and sides of the chest became the seat of huge pendulous masses, firm yet elastic, in places finely lobulated and feeling like bundles of worms. Menstruation had begun at 15 and had ceased abruptly at 35. Microscopic examination of a bit of tissue removed from one of the swellings disclosed the presence of only fat and connective tissue. The case was described as one of *subcutaneous connective-tissue dystrophy* associated with symptoms resembling myxedema. In a subsequent communication Dercum³ reports in greater detail both of the foregoing cases, together with a third, describing them as "three cases of a hitherto unclassified affection resembling in its grosser aspects obesity, but associated with special nervous symptoms," and proposing for them the name of *adiposis dolorosa*. The third of these cases occurred in a widow, 60 years old, who had for many years had soft, fat-like masses or swellings in various parts of the body that were painful to touch. Cutaneous sensibility was diminished and the patient was demented. Death resulted from gradual failure of vital force and the thyroid gland was found to be enlarged, indurated and calcified. Death occurred also in the first of these cases and the thyroid was found likewise indurated and calcareous, although small.

In the article on *adiposis dolorosa* in "A Text-book on Nervous Diseases by American Authors,"⁴ Collins refers to six cases under the observation of Peterson and Loveland and to one under his own observation. He states that all of the cases but one occurred in women from 40 to 60 years of age; that in but one could a specific or alcoholic history be ruled out, and that in all a neuropathic predisposition was evident.

In a consideration of the treatment of myxedema, cretinism, exophthalmic goiter, obesity, etc., with thyroid extract, Ewald⁵ refers to the case of a man, 47 years old, weighing 217 lbs., who presented a puffy appearance, with thick masses of fat about the nipples and the umbilicus and upon the neck, and pains resembling those of neuritis. Perspiration was scanty and the condition was suggestive of myxedema, though wanting in the characteristic features of this disorder.

Spiller⁶ has reported three cases of *adiposis dolorosa*, all in women, two unmarried and aged 25 and 65 respectively, and the other married and 45 years old. In the first there were both diffuse enlargement and distinct painful swellings, with paroxysmal exacerbations. Menstruation was normal. In the second case the patient began to grow stout at 40, when menstruation ceased. For thirteen years there had been pain in the lower extremities, and for two years in the fatty

tissue of the limbs and trunk, with paroxysmal exacerbations. The obesity had increased markedly since the advent of the latter pain. There were tenderness and pain on palpation, manipulation and pressure, and no anesthesia. The fatty accumulation was marked on the thighs, the calves, the abdomen, the nates and the back, and also in the arms, though less in the forearms and absent from the feet and the hands. There was no special deposit of fat and no pain in the face or neck. The isthmus of the thyroid was exceedingly small. The third patient had been corpulent for twelve or thirteen years, following the birth of her last child. Pain had been present for years, recurring in paroxysms. Swellings appeared beneath the skin of the lower extremities, at first small, then larger and finally diminishing in size. Sensibility was preserved and the face was not involved. Improvement followed massage and the administration of thyroid extract. A cross-section of muscle from one of these cases showed no appreciable deviation from the normal, except perhaps a slight enlargement of the nuclei.

To this small number of cases I am able to add a further one, and also the notes of a case kindly placed at my disposal by Dr. Dercum:

M. G., a married white woman, 48 years old, was admitted to the medical department of the Philadelphia Hospital June 6, 1896, and shortly afterward the following facts were elicited: Her mother had been dropsical and had died at the age of 86. Her father and one brother had been killed in war. Two other and older brothers were alive and well. A sister also was living at the age of 60 years. Another sister had died in a dropsical state. The sister and one brother were said to be stout, but within ordinary limits. A maternal great-grandmother also had been unduly stout. The patient related that she had suffered from attacks of erysipelas of the lower extremities on four different occasions, the first at about the age of 30, the second six years later, the third at some forgotten time after, and the fourth a year before coming under observation. She had borne five children, all delivered instrumentally. Of these one had died during birth and another of diphtheria; of the remainder one boy and one girl were spare and a daughter of 28 was stout. Her husband had died of pneumonia eighteen years previously. Menstruation had begun at the age of 13 years and had been regular and painless until the age of 41, recurring thereafter with increasing frequency and being attended with excessive hemorrhage. At the age of 35 the patient is said to have broken down from overwork and worry. At this time twitchings were observed, and a sense of such movements had persisted thereafter. After an interval of uncertain length the woman noticed enlargement of the abdomen. Then the lower extremities became involved, the increase in size extending gradually and progressively over the entire body, with the exception of the face and the hands and the feet. The patient had suffered a good deal from pains in the back, especially in the sacral and interscapular regions. The pain was intermittent and had set in with the accumulation of fat. For more than two years there had been a more or less constant sensation of beating in the head, and for a year or more ringing in the ears. There was no vertigo, and auditory perception was good. The appetite was preserved; it had never been excessive, and the patient had no preference for, nor had she indulged in, special kinds of food. There was at times nausea and occasionally vomiting, the ejected matters sometimes containing blood. For more than a year the patient had been helpless, being compelled to lie abed and unable to move about. She occupied two single beds in the hospital and was scarcely able to help herself in any way.

On examination at the time of admission to the hospital heart and lungs were found to present no abnormality. The face was scarcely larger or fuller than that of a person of ordinary size. The circumference of the neck was 17 inches, of the bust 60 inches, of the waist 53 inches, of the abdomen 70 inches, of the arm above the elbow 21.5 inches. The temperature, taken for months at a time, adhered to the normal level; the respirations fluctuated between 18 and 32, averaging perhaps 24; the pulse ranged between 68 and 108, averaging about 84. The urine, examined repeatedly, displayed a specific gravity between 1019 and 1028 and, other than the presence of a small number of leucocytes, exhibited no deviation from the

⁶ Medical News, Feb. 26, 1898, p. 268.

normal. On examination on June 18, 1897, the hands were observed to be well nourished, but of ordinary size. The circumference of the forearms above the wrist was 7.25 inches, below the styloid processes 6.6 inches. At the elbow there were marked creases on the dorsal and palmar aspects. The circumference 1 inch below the flexure was on the right 13.75

der. The fat of the neck was not markedly increased. The breasts were large and extensive, though flat, falling in huge apron-like folds. The right appeared to be larger than the left and its pigmentation was the more pronounced. The mammillary areolæ were marked, and also the tubercles. The circumference of the trunk at the waist was 41 inches, at the level of the

inches, on the left 12.5 inches. There was only a small growth of hair in the axilla. The mid-humeral circumference on the right was 16.5 inches, on the left 16 inches. The upper extremity was strikingly conoidal in form, with the base at the shoul-

sacrum 59 inches. The distance from the olecranon process of the ulna to the styloid process was 10 inches, from the acromion to the olecranon 13.75 inches. The circumference at the middle of the thigh was 31 inches. The distance from the outer

margin of the patella to the external malleolus was 16 inches and to the outer extremity of the inguinal fold 17 inches. The circumference at the middle of the leg was 17.5 inches. The right foot was 9.75 inches long, the left 10.25 inches. The surface of the skin was mottled, purplish and cyanotic on the right side of the body, on which the patient lay. The heart sounds were quite clear and distinct. The tongue was broad, fissured and tremulous; the patient stated that it had always presented a similar appearance. The ears were not enlarged. The thyroid gland could not be felt. The hair was soft and unctuous. The skin also was soft, and perspiration was free. The masses of fat yielded a cord-like sensation to touch, and manipulation elicited tenderness. The patient had received varied treatment, without appreciable effect. For a time desiccated extract of thyroid gland was prescribed, 5 grains twice daily, but in a short time the patient declined to take the medicament, complaining, among other things, that she had been poisoned by some of the drugs she had received. Subsequently she developed pronounced delusions and it became necessary to remove her to the department for the insane.

ladder and wounded the right leg above the ankle with a rusty nail. Symptoms of lymphangitis developed, from which recovery ensued. Three months later the left leg was wounded as the result of a fall and it became inflamed and increased in size. The enlargement extended upward, and in a short time the right leg also began to increase in size. The hyperplastic parts became the seat of cracks and fissures and indolent recurring ulcers. The illustrations accompanying the report show great enlargement of the legs, thighs and abdomen, with immense buttocks, full shoulders, while the face, feet and hands were relatively small.

As an instance of a further anomalous form of *obesity* may be mention a case reported by Adler,⁸ occurring in a mulatto, 53 years old, with a syphilitic history,

While it may be objected that this case is lacking in some of the symptoms of *adiposis dolorosa*, as laid down by Dercum, it will be conceded that it is unlike an ordinary case of obesity. The principal accumulations or deposits are nearest the trunk and they hang in conspicuous folds, while the degree of incapacitation for the simplest activity is extreme. Pain has not been a prominent symptom and we have no knowledge of paroxysmal variations in the degree of enlargement, but the patient's memory was not reliable and her statements were at times wanting in positiveness. The case is in some respects not unlike one reported by Laidlaw⁷ as an example of *elephantiasis*, occurring in a woman, 45 years old, who in the performance of some laborious task at the age of 27, suffered an injury of the abdomen near the umbilicus. The cutaneous and the subcutaneous tissues of the affected parts became reddened, swollen and infiltrated. The acute symptoms soon subsided, leaving well-marked hypertrophy, which gradually diminished. Two years later the left leg became covered with scales and enlarged, and the abdominal condition grew gradually worse. Seven years after this the woman fell from a

but with none of obesity in the family, who presented an enormous growth in the middle line at the back of the neck, two smaller bilateral masses symmetrically situated in the occipital region, another in the middle line below the chin forming an immense dewlap and extending up into the parotid regions, one in each groin absolutely symmetrical and projecting forward as well-rounded swellings. A more diffuse fatty deposit was present on the arms and forearms. There was one unilateral tumor over the left rectus muscle above the level of the umbilicus. The several growths were movable and free from pain, while the overlying skin was tense and unadherent.

I am indebted to Dr. Dercum for the following notes:

A married woman, 36 years old, in excellent health and free from physical abnormality, while standing in the aisle of a trolley car, was thrown to the floor as the result of a collision with a heavy wagon and at once became unconscious. She was sent home in a carriage and was subsequently unable to move without assistance. Later she was able to sit up in a rolling-chair and got about with the aid of crutches. A miscarriage took place fourteen days after the accident. The patient suffered greatly from pain. When examined, a year after the accident, she could not stand without assistance, although she could

⁷ Jour. of Am. Med. Ass'n, vol. xxvii, p. 165.

⁸ Pacific Medical Journal, September, 1893, p. 529.

walk with the aid of crutches. Superficial pressure over the spine in the lower dorsal, lower lumbar and sacral regions and also over the coccyx induced pain, and deep pressure over the muscles of the back of the trunk in the lower dorsal and lumbar regions on the left side, and in less degree on the right side, elicited tenderness. Similar tenderness was noted also on the left side of the chest. Transmitted shock caused pain referred to the lumbar region, flexion of the trunk pain referred to the same region, and especially lateral flexion to the left. Attempts to extend the legs, with the patient seated on a chair, induced pain referred to the back of the legs and thighs. The knee-jerks were exaggerated. There was some analgesia of the left arm, left leg and left side of the trunk, but no inflammatory or ovarian tenderness, and no limitation of the visual fields. Upon the left forearm there were found seven or eight small swellings, varying in size from a small marble to a walnut, soft to the touch and apparently made up of fatty tissue. These were exceedingly painful and tender on pressure. The patient was positive that they had made their appearance some six weeks after her accident, when she became aware of the presence of several slightly swollen and tender places upon the left forearm. These had increased in size and continued to be painful. The patient suffered from occipital headache, from a sense of constriction of the head, from vertigo, at times from ringing in the ears and from backache, relieved by the recumbent posture. She slept badly, having difficulty in getting to sleep and being disturbed by frightful dreams. She felt worse in the morning on arising than at night on retiring. She suffered from indigestion and chronic constipation. Palpitation of the heart was frequent, especially after unpleasant dreams. Micturition was increased in frequency, particularly at night. Perspiration was induced by slight exertion. On examination, some nine months later, it was found there had been some subsidence of the symptoms indicative of spinal strain. The painful masses upon the left forearm were still present and had undergone no appreciable change in size. There were now noticed, in addition, several large, diffuse swellings upon the lower portion of the back and in the sacral region. These were soft and painful and tender on pressure, and like the others, although larger.

As defined by Dercum,⁹ *adiposis dolorosa* is a disorder characterized by irregular, sometimes symmetrical, deposits of fatty masses in various portions of the body, preceded or attended with pain. It appears about middle life or later and the larger number of cases have occurred in females. In some there been an alcoholic history, in others a syphilitic history; in still others rheumatism may have been an etiologic factor; further, traumatism may be a provocative agency. Nothing more definite, however, can be said of the etiology. The principal manifestation is the presence of masses of fatty tissue of variable size, sometimes exceedingly large, variously distributed upon the trunk and the extremities, and the seat of pain sometimes spontaneous, sometimes induced by pressure or manipulation. The affection may set in with pain of neuritic character and the swellings may undergo increase of size in paroxysms attended with exacerbations of pain. The new fatty tissue has a boggy, soft, at times pultaceous and wormlike, feel. Face, hands and feet are not involved. In some cases sensibility is impaired. The skin exhibits no gross changes. Hemorrhages from mucous surfaces have been observed in some cases. The disease is essentially chronic, with a tendency to be progressive in course. The morbid anatomy consists, so far as is known, in an increase of fatty and connective tissue, with degenerative changes in nerves. The thyroid gland has been found indurated and calcareous. The disorder differs from other forms of obesity in the presence of pains and sometimes of impaired sensibility; and from myxedema in the freedom of face, hands and feet and in the absence of the pronounced mental and trophic manifestations of that disease. In treatment good results may be expected from administration of thyroid extract and from massage.

⁹ Twentieth Century Practice, vol. xi, p. 554.

SOME CONSIDERATIONS OF THE SYMPTOMATOLOGY IN THE DIAGNOSIS OF TABES.

Presented to the Section on Neurology and Medical Jurisprudence, at the Forty-ninth Annual Meeting of the American Medical Association, held at Denver, Colo., June 7-10, 1898.

BY J. M. AIKIN, M.D.

Neurologist to the Methodist Hospital, and Clinical Lecturer on Diseases of the Brain and Nervous System, in the Creighton Medical College.

OMAHA, NEB.

About two years since, a physician doing a large practice in general medicine, impressed me wonderfully with the statement that seven cases of locomotor ataxia had come under his observation and treatment during the preceding three months. Of these, five had completely recovered, one died after three weeks' illness, from inability to swallow food, and one was convalescent. My disbelief in the curability of tabes induced me to seriously consider the *alleged* prevalence of the malady as truly alarming, whereupon I began investigating vital statistics from several of the large cities of the United States, and found that in the whole number of deaths reported as due directly to some form of nervous disease, only about 1.2 per cent. was accredited to locomotor ataxia. Reviewing some cases neurologic in character, that I was permitted to observe and treat during the five years preceding 1897, the shortest period for observation, in any one case being one year, I was unable, in seventeen out of twenty-three alleged cases of locomotor ataxia, to verify the diagnosis.

The observation of symptoms in disease is quite as necessary as the accumulation of evidence in a legal case, and a knowledge of their meaning is certainly no less imperative in forming right conclusions, than is the action of a judicial mind in estimating the value of testimony in a case at law. Moreover, clinical evidence in disease is quite as truthful as testimony at the bar, while microscopic findings certainly can not be more liable to error than twelve jurors, each exposed to ulterior influences.

During the past few years, the surprising advance of medical minds in the pathogenesis of nerve tissue per se is without a parallel in any branch of medicine, or period in its history. I therefore proceed—with a confidence maintained not alone by self-gleaned facts, but supported by truths, the authenticity for which many medical men in this ASSOCIATION deserve honorable mention—to assume that neurologic medicine has established a basis from which a proper estimate of the evidence, in at least the more common diseases of the nervous system, may render serious mistakes in diagnosis unpardonable.

The activity shown by American physicians recently, in placing before the public so many excellent text-books and essays, treating especially of the features of nervous diseases, gives assurance irrefutable that those already in active practice have easy access to the latest information on this class of diseases.

The American propensity to observe, and inquire into the meaning of the thing seen, has placed him as a leader of the world in his observation and knowledge of the phenomena of the nervous system. Clinical evidences in individual instances of nervous diseases presenting varying symptoms, are accumulating and must accumulate until, by comparison and elimination, we arrive at the characteristics of a type, as has years since been done by internal medicine in

some of the exanthematous diseases—e.g., measles and scarlet fever—which shall be accepted and accorded a place in medical nomenclature.

Early observers discovered and recorded symptoms indicative of some grave disorder of the nervous system, but not until about half a century since was any exact account given locating the pathology productive of these symptoms in the spinal cord, thereby elevating the group to the dignity of nosologic consideration, and ten years later the name "locomotor ataxia" was coined. This term was an unfortunate one, in that it fails to convey anatomic location, or character of the neural changes, but further, in that it does afford the incompetent or careless observer a convenient peg on which to hang every case of nervous phenomena presenting sensory disturbances with pain, or difficulty of locomotion unless by constantly watching the placing of the feet. If perchance, too, the knee-jerk is absent, the testimony closes and the label "locomotor ataxia" is attached.

No member of this ASSOCIATION would venture a diagnosis on the foregoing clinical history, but I doubt not many physicians present have seen and treated patients whose lives had been rendered more miserable by long-continued treatment for locomotor ataxia, when in reality they were suffering from some other, and possibly curable, malady of the nervous system. The chronicity, too, of tabes, carrying the patient through periods of time measured only by months and years to the full development of its clinical picture, may so separate the sign-boards along the route, as to allow the most experienced clinician an opportunity for error in conclusions; whereas in our observation of acute diseases such errors are less likely, because we are accustomed to reviewing the whole course of the malady in a few days, or at farthest weeks, of time. No other chronic disease of the nervous system is so much talked about by the laity, lawyer or incompetent physician, and like ovaritis and appendicitis, the frequency with which tabes is diagnosed gives cause for doubts as to a right observation and interpretation of symptoms. The indefiniteness of the name enhances its popularity, and the chronicity of the malady makes it a convenient receptacle for all symptoms suggesting cord disease, the incorrectness of which may be difficult to demonstrate. Moreover, the cerebral vagaries and spinal symptoms incident to a depreciated condition of the nervous system may cause—not alone in the inexperienced physician—a suspicion of tabes, thereby casting an irreparable gloom over the mind of a person afflicted with the modern and euphonious neurasthenia.

Early recognition of tabes is desirable not alone in our treatment, but for prognosis; yet the wider our observation of cases, the greater is our surprise at the multiplicity of the symptoms and their order of appearance, often causing the most accurate observer some anxiety in making a diagnosis, until he has made repeated examinations, or can at one sitting get a complete and intelligent clinical history covering a long period of time; for until degeneration has begun in the cord, symptoms presenting indisputable evidence of the malady are wanting. The sensory symptoms, so often preceding any motor manifestations, are frequently regarded as rheumatic, and if accompanied by digestive disorder with occasional vomiting, may cause our attention to be fixed on chronic gastritis with muscular rheumatism. We would be surprised at our easy transition to a different conclusion, if on

closer examination we have revealed to us a fact, that the pains are confined to the lower extremities, intermittent in time, and lancinating in character; while the vomit appeared at intervals wholly independent of the time when food was taken, and was not immediately preceded by nausea or gastric distress. In the event of such evidence, we may justly suspicion a case of tabes. Moreover, symptoms essential to the complete clinical picture, but as yet not fully developed, or having appeared, are forgotten or considered by the patient as being wholly unimportant, may be brought into view by a careful retrospective history of the case. If the ataxic condition is uppermost in the patient's mind, and is especially annoying during his nocturnal excursions, he may be entirely unconcerned about the occasional darting pains in the bladder, bowels, rectum or anus, and ready to explain the paroxysms of dyspnea or motor impairment of the glottis as a result of "a little cold," but in the absence of pulmonary cardiac, cystic or bowel disease, such symptoms having existed or now present should form collateral testimony of positive value in the tabetic. If peripheral limitation of vision is noticed, the onset being rapid, then gradually retarding in progress until months pass before perceptible changes in the field of vision are noticed, the seeming stay of progress should not lend strong hopes for a favorable issue, since gray degeneration of the optic nerve in tabes is first rapid, then retarded, and usually centripetal in course. Pupillary reaction to light is lost. As between the hyperesthesias, anesthetics, paresthesias and pains of tabes, we may rightly regard the latter as the earliest to appear, most annoying in character, and persistent in duration. They are lancinating, come without warning, and are prone to greater severity at night, but unaccompanied by febrile disturbance and not of the short duration commonly seen in the early stage of a multiple neuritis. Impairment of sensation, though most frequent and of greatest severity in the lower extremities, may first appear elsewhere.

In the records in my case-book, appears the evidence in the case of a physician under my care for four years, whose early pains were in the back and hip muscles; he also complained of a sense of constriction of the body, but unmarked by a zone definitely localized. If anesthesia be present in any case under observation, it is interesting to note its extent, for in tabes it will invade the deeper tissues as well, and muscular contraction by the electric current, or the pains of pleurisy, may be unfelt. Another point of great value in differential diagnosis is the presence of inco-ordination of movement, without loss of motor power; this is a characteristic of tabes, and may for months or years precede all sensory disturbance.

Again, the early manifestations of motor disorder may have been so lightly considered by the patient as to have escaped his notice, or been forgotten when suffering from subsequent lightning pains; this can be easily accounted for, because motor power was not impaired, but the evidence is of paramount importance when we remember that ataxia in tabes differs in nowise from inco-ordination incident to combined lateral and posterior column sclerosis, but in this latter, a history of muscular weakness, with *early* exaggeration, then subsequent loss of knee-jerk, is the rule, whereas in tabes increased knee-jerk never occurs, and its disappearance is an early symptom.

Absence of the knee-jerk and the existence of ataxia.

are essential features in the clinical picture of tabes, yet their appearance in so many non-tabetic affections of the nervous system tends to nullify their importance in differential diagnosis, unless they are stable, and supported by other evidence.

Articular enlargement, pointed out by Charcot and insisted upon as frequently an early symptom, has been verified by several medical gentlemen of note, and merits our careful observation, as its presence may be the one symptom needed to the unfolding of a true case of tabes. I have been unable to verify, and am unwilling to accept as true, the statement recently current in several medical journals, that absence of pain in the popliteal space, on extension of the leg with extreme flexion of the thigh, is an early and positive proof of tabes; since the same clinical effect may be produced by a traumatism or disease limited to the anterior crural nerve. If of differential diagnostic value at all; its existence must be bilateral. Moreover, the absence of knee-jerk as a common factor in either affection cancels its diagnostic value, while motor weakness and muscular wasting—if present—negative any tabetic assumption. In a large percentage of tabetics the ataxia is a late symptom, and in such cases it is doubtless true that the lancinating pains are more constantly accompanied by optic atrophy and arthropathies.

Localized sweating was a noticeable feature in two cases under my observation. The first was unilateral in extent, the second was limited to the face, neck and arm of one side. The first one of these was seen by Dr. C. K. Mills of Philadelphia, who verified our diagnosis and noted this peculiar vasomotor disturbance. That this symptom belongs peculiarly to tabes remains an open question, for other cord or spinal nerve root affections may find *direct* expression in the same symptom or through the sympathetic system. In either case its differential diagnostic value becomes void.

THE THERAPEUTIC VALUE OF THE VARIOUS ANTI-MALARIAL AGENTS.

Presented to the Section on Materia Medica, Pharmacy and Therapeutics, at the Forty-ninth Annual Meeting of the American Medical Association, held at Denver, Colo., June 7-10, 1898.

BY J. R. GILBERT, M.D.

DALLAS, TEXAS.

Under this title we must at least give a limited number of drugs a hearing, though it be near impossible to consider each that has been given as an anti-malarial agent, for most, if not every drug found in the materia medica, has at some time received credit for its anti-malarial effect upon the human economy.

Before we enter upon the therapy of the subject of malaria, we should know what the pathology of the trouble is, so that we may intelligently administer those remedies that will the earliest counteract or destroy the pathologic condition that exists, with the least detriment to the human organism.

We know that when a person is inoculated with this bacillus malariae, he will surely have a malarial fever. While there is a slight difference in the germs that cause the various forms of malarial fever, they are practically the same, for the agent that will destroy one will also destroy the other. There have been a variety of opinions expressed as to how this organism enters into the blood. Some are earnest advocates of the avenue of entrance being the air-passages, and others the alimentary canal. And those who calmly

sum up all of the evidence and weigh it well in the balance, must be forced to the conclusion that the malaria bacillus enters both by the lungs and alimentary canal. One may become infected from water, another from food; and he who sleeps in a low altitude inhabited by this germ will most surely become the victim of this familiar disease, malaria.

Since we know what our condition is, when to look for paroxysms, and their cause, the next thing to consider is whether we can find, in our great armamentarium, an agent that we can diffuse into the blood of our patient, which will destroy the bacillus, and at the same time not do material damage.

When we look over the past, we find the housewife and the physician both endeavoring to administer to the wants of the wretched mortal who is apparently trying to shake the cords out of the old bed. One in his or her effort is drenching the poor sufferer with hot teas when he is already afire, another giving some herb that *they say* is good for *chills*. On and on they went, until at last, by mere accident, the great specific was discovered.

There are but few diseases for which we possess anything near a specific, but to the great relief of suffering humanity, we have ever ready in our armamentarium that drug which, when administered so that it may become diffused into the blood, will destroy the *bacilli malariae*, and do no hurt to the cells that go to make up the human body. This drug that is known in every household is *quinin*. Now, since we have a specific for the disease in consideration, it only remains to consider how it should be administered to attain this end and the helpful adjuvants, and last but not least, what we are to do when the patient's idiosyncrasy positively prohibits the use of our great boon to humanity.

Quinin, the great prime agent, has been administered in many different ways, and every recent textbook gives the various methods of administration and suggests the best way of administration, and those who are without experience in treating malarial fevers will find there are those minute points of technic that are only acquired by experience that they must learn.

I will say nothing of the way to administer this drug by the stomach, because I can add no more than all good, recent authors have laid down as rules to follow. I will make a few suggestions on the two much-neglected methods of quinin administration, viz., hypodermic and intravenous. It is only to those who live in the intensely malarious districts that these two methods will be of much interest practically, for stomach administration will suffice in all mild cases, as this drug will be taken up by assimilation; but when the physician is called to see a patient with a malarial paroxysm that is commonly called a congestive chill, and perhaps has reached that state of malarial hematuria and hematemesis where absorption or assimilation through the natural avenues is impossible, we must then reach our conclusion very rapidly for the bacilli malariae are causing such a combustion in the blood that the life of the individual will soon be gone, unless we can introduce into the blood that agent which will destroy the bacilli.

Hypodermic use first suggests itself to us, and when we take the soluble salts of quinin, such as the muriate, we can usually get enough of the drug into the circulation to destroy the great adversary. But sometimes we are too late to depend upon even the hypodermic injection into the subcutaneous tissue, for

death is so near at hand that the circulation is not sufficient to carry the drug into the volume of blood of the body from the capillaries. In this our dire extremity, if we inject a quantity, say a half-dram, into a vein, and use circulatory stimulants, we may often rob the grave of a victim.

The great object to be ever kept in view, for all know how to administer, is that if you can get this great germ-destroyer into the blood in time, where the germ of malaria is only found, you can save that poor mortal from an untimely grave. Then it becomes our duty to familiarize ourselves with the methods of hypodermic and intravenous medication.

For those who have the idiosyncrasy for quinin we will find salicin and salicylate of soda of great advantage. When given in large doses, it will have quite a satisfactory result. But fortunately for all, we seldom find a patient who will not stand some of the salts obtained from the Peruvian bark.

In old chronic cases it is necessary to give something else attention beside the disease germ. For after a person has long been the victim of malaria, he is sure to suffer from some weakened organ that has received the brunt of the burden in carrying the great and complex machine through the siege of poison that has been pouring acid on the polished plates and rusting the surface until it has overworked and loaded up the liver, kidneys and spleen, until a few more months among this poison would return them whence they came. This brings us, not to anti-malarials, but to that part of our armamentarium marked alteratives, and from them we select those best suited to the individual case. Arsenic and iodine will often be our selection, for in them we find that while we restore organs to their natural function we brace and tone up the nervous system, that has been shaken around for months, and made subservient to all emotional and outside influences.

There are other alteratives that will to some degree answer our purpose, but those are exceptional cases where arsenic and iodine will not render most good in chronic malaria. So, in our summing up of the therapeutic value of various anti-malarial agents, there are few drugs we need consider. We have the specific for the malarial poison, and by closely studying the complications and administering to them properly, we will relieve many who now suffer from crippled organs caused by long-continued malarial fevers.

TREATMENT OF CONGENITAL TALIPES

Presented to the Section on Diseases of Children at the Forty-ninth Annual Meeting of the American Medical Association, held at Denver, Colo., June 7-10, 1898.

BY HARRIET E. GARRISON, M.D.

DIXON, ILL.

As I am not an orthopedic surgeon, in assigning me the task of preparing a paper upon the treatment of congenital talipes our worthy secretary has given me a burden which I feel unable to carry. What I desire to present to this society are the results obtained in the immediate treatment of the very few cases of congenital talipes which have occurred in my obstetric practice. It does not usually fall to the lot of a country practitioner to have many cases of congenital talipes, but we meet them occasionally at the most unlooked-for times and places, and it behooves us to be prepared for the unexpected.

One of the great benefits to be derived from a country practice is the necessity for alertness to recognize

and preparation to cope with any form of disease or surgical emergency, for at the time there is the greatest demand there is the least opportunity to procure a skilled specialist. Unless a physician is willing to give patient study to every branch of medical science he should never become a country doctor. For twenty years I practiced obstetrics in my general country work without meeting a case of talipes, and then in fifteen months I had three cases.

Case 1.—I was in the country, six miles from my office, and although I bathed the child I did not notice anything abnormal. The second day the father visited my office to tell me he thought one of the baby's ankles was out of joint. I immediately visited the child and found the right foot abducted to the third degree of talipes. There must have been an increase in the abnormal position since my visit or I could not have failed to notice it in the bath. The abduction had produced luxation of the joint, as I could feel the articulating surface of the tibia grate upon the os calcis and astragalus as I made gentle pressure on the joint with thumb and forefinger of the left hand, while I slowly drew the foot into position with my right hand. The foot and leg had previously been bathed in very warm boracic acid solution and, while held in position slightly adducted, was bandaged lightly with a narrow gauze roller bandage from the toes to near the knee. The bandage was then dampened and a little plaster-of-Paris dusted over it and allowed to dry while the foot was held in position. The dressing was left in position two weeks and then was removed by the mother. The mother was directed to keep watch of the baby's toes, that they remained the right color, that there might not be any danger from the pressure; and she was instructed how to apply gentle massage to the joint and adductor muscles every day after the bandage was removed. I did not see the child until it was nineteen months old, when it was brought to my office for treatment for the ankle, which was swollen and tender, from a wrench which had been given it by the child catching its foot in between two boards. The faithfulness with which the mother had carried out the massage treatment could be seen in the superior development of the muscles of the right leg over those of the left. There was still slight extension of the foot on the ankle, but not as much as in the left leg. The child had walked from the twelfth month. This extension of the foot on the ankle and a slight tendency of the shoes to wrinkle on the inside was all that remained of the talipes. As the child was wearing cloth buttoned shoes I advised a well-fitting pair of leather, laced, and if these wrinkled, to have the inside further strengthened by a piece of stiff leather.

Case 2 was five miles in the country in another direction from No. 1, and was a case of talipes calcareus, with the extension surface of the toes resting against the foreleg; this was accompanied by flat foot. The outer and inner extensor tendons of the foot were contracted until they stood out like whipcords, and the deformity seemed due to this contraction and a little displacement of the fourth tarsal bone. The foot could be easily brought into position, which was all the treatment given on the day of birth, with direction to the nurse to draw it into position whenever the baby received attention. As there was no improvement on my visit the second day, I replaced the tarso-metatarsal articulation, applied a pad of folds of gauze over the joints and bandaged from toes to above the ankle while the foot was in correct position. This held the foot properly and the nurse was directed to keep it on as long as it stayed in place; but to notify me as soon as there was any appearance of displacement of the foot. I saw no more of the child until it was over five months old, when I went to the house for the purpose of inspecting the foot, and could not tell which foot had been deformed, as they were both straight and used with the same freedom and correct movement.

Case 3 was double equino-varus of the first degree, complicated with bow-legs and knock-knee. As the child was given in care of a trained nurse, and as she did not think the condition serious enough to need any attention, nothing was done until the child was a month old, when I was called to clip the frenum linguae for tongue-tie. At this time the mother called my attention to the fact that when the baby contracted its feet they turned in and never out. I pointed out the curvature in the legs and tendency of the knees to come together and advised a system of massage to strengthen the muscles of the legs. In the course of six weeks, the mother told me, that the feet were just as likely to turn out as in when flexed. At the present time, six months later, the legs are very much straightened and there is no appearance of talipes.

It hardly seems worth while to dwell on the probable cause of this condition in the three infants, but the same factor was present in all three—mothers below the normal and fathers tall. This was especially noticeable in Case 3, as the mother's regular weight is 95 pounds and father's 175. The child weighed 8 pounds and was 19 inches long. Cases 2 and 3 both had a prominent vertebra. The twelfth dorsal vertebra was prominent, as though the spine might have been sharply flexed at this point during intra-uterine life. In these cases the mothers were instructed to apply extension to the spine every night by placing the child across the knee with the shoulders and hips suspended and at the same time to apply gentle massage the full length of the spine and legs. I have never found a mother who was too careless or lacked sufficient intellect to apply the massage systematically, after the benefits to be derived from it had been explained.

In the treatment of congenital talipes my experience leads me to believe that the earlier it is begun the more easily the balance between the antagonizing muscles is restored and that every child's feet should be critically examined to see if the muscle-balance is even, and if not, efforts to restore it should begin immediately.

RECENT EXPERIENCES IN MILITARY SURGERY AFTER THE BATTLE OF SANTIAGO.

ON BOARD THE HOSPITAL SHIP "RELIEF," JULY 22, 1898.

WOUND INFECTIONS.

Military surgery is no more nor less than emergency surgery in civil practice. The surgeon in daily practice has learned long ago that every accidental wound must practically be regarded and treated as an infected wound. In this respect the military surgeon of today has the advantage over his colleague in civil practice in knowing that the small caliber bullet inflicts wounds which *per se* are more often aseptic than septic. Our recent experience in Cuba has shown that the small jacketed bullet seldom carries with it into the tissues clothing or any other infectious substances. Most of the wounds of the soft tissues, uncomplicated by visceral lesions, which in themselves would become a source of infection, healed by primary intention in a remarkably short time. If infection followed it usually did so in the superficial portion of the wound in connection with the skin, and what is more than suggestive, the wound of exit was more frequently affected than the wound of entrance. This can be readily explained from the larger size of the wound and more extensive laceration and tearing of the tissues. In many of the cases ideal healing of the wound did not occur, owing to a subsequent limited superficial suppuration of the wound. The deep tissues were seldom implicated in such cases. I have reason to believe that some of the compound fractures which are now suppurating had such a source of infection, that is, the extension of a superficial infection to the seat of fracture. Two weeks have now elapsed since the battle of Santiago was fought and we are now in a position to inquire more critically into the manner in which the wounds became infected. The many failures in protecting the more serious wounds against infection are attributable to three principal causes: 1. Inadequate supply of first dressing. 2. Faulty application of first dressing. 3. Unnecessary change of dressing. The medical officers with the regiments and in the field hospitals were hampered in their work by an insufficiency of proper material. The rapidity with which the invasion was planned and executed, the difficulties encountered in transporting the hospital supplies to the front and the unexpected large number of wounded readily explain the lack of dressing material when

it was most needed. Many of the dressings were too small and not sufficiently secured to keep them in place in transporting the wounded from the front to the field hospitals. As a rule, not enough attention was paid to the immobilization of the injured part, an important element in securing rest for the wound and in guarding against displacement of the dressings. It is a source of regret that plaster-of-Paris dressings were not more frequently employed in the treatment of gunshot fractures of the extremities. Another very palpable evil in causing infection was the too common practice of unnecessary change of dressing. The transfer of patients from one surgeon to another could not be avoided. Patients brought from the first dressing station to the field hospital usually were subjected to a change of dressing and, when a few days later they reached the General Hospital at Siboney, they had to undergo the same ordeal and often not only once, but as often as they came into the hands of another surgeon. Patients not thus treated were dissatisfied, as the laymen are still laboring under the erroneous impression that the oftener a wound is dressed the quicker it will heal. It is difficult to eradicate such a deep-rooted and time-honored belief, and patients will continue to clamor for a change of dressing, and the good-natured, hard-working surgeons only too often yield to such unreasonable requests. The evil of meddlesome surgery has become very apparent during our brief Cuban campaign and has taught us an important lesson that must be heeded in the future. Our military surgeons must learn to realize the value and importance of first aid dressing. In all cases where the first examination does not reveal the existence of complications which require subsequent operative treatment the diagnosis tag should convey this important instruction: "*Dressing not to be touched unless symptoms demand it.*" Such instruction is significant and must be followed to the letter by all surgeons in subsequent charge of the patient.

I am satisfied more than ever of the necessity of including in the first-aid dressing package an antiseptic powder. For years I have used for this purpose a combination of boracic acid and salicylic acid, 4:1, with the most satisfactory results. I am also partial to sterile absorbent cotton for this particular purpose, as it constitutes a more perfect filter than loose gauze. A teaspoonful of this powder dusted on the wound forms with the blood that escapes and the overlying cotton a firm crust, which seals the wound hermetically. Should the primary dressing become saturated with blood, the same powder should be dusted over the wet dressing, and an additional compress of cotton is added to the dressing. After the first dressing has been applied it should not be removed except for good and substantial reasons. Much can be done in the after-treatment in the way of adjusting the bandage and in immobilizing the injured part, but the first dressing must remain unless local or general symptoms set in which would warrant its removal. Malaria and yellow fever, that crept in upon us so insidiously, are responsible for many unnecessary changes of dressing. The appearance of fever in a wounded man naturally leads to the suspicion that there is something wrong in the wound. Many dressings were changed on this ground, nothing abnormal was found in the wounds, and a day or two later the nature of the fever was recognized and the patients were either given quinin or were sent to the yellow fever hospital, in accordance with the diagnosis made. *Every change of dressing, more especially in military practice, is attended by risk of infection and must be scrupulously avoided, unless local or general symptoms indicate the existence of complications which demand surgical intervention.* In writing the above it is not my intention to cast any reflection on the work of our surgeons; on the contrary, I willingly bear witness to the ability, faithfulness and unselfishness with which they have done their duty. A better and more conscientious group of medical officers it would be difficult to select anywhere. The results on the

whole are excellent, but I am hopeful that they can be improved in the future by placing more stress and attention to the value and importance of the first dressing, and wish to repeat again and in a most forcible way the language of the late Professor von Nussbaum: "*The fate of the wounded rests in the hands of the one who applies the first dressing.*" If this is true in civil practice, its meaning can not be misinterpreted in military surgery.

EFFECTS OF BULLETS ON THE SOFT TISSUES.

In recent cases the small tubular wound made by the Mauser bullet was surrounded by a narrow zone of contused tissue, and the wound space itself filled either with liquid or coagulated blood. A few days later the wound itself was found surrounded with an area of saggillation, which varied in extent according to the nature of the tissues and the amount of extravasation. In cases in which the bullet passed through the tissues some distance, and not far from the surface of the skin the location and direction of the wound canal was indicated by discoloration of the skin a few days after the injury occurred. In a number of cases of aseptic wounds in which the bullet had lodged in the tissues and was removed a week or ten days later, I had an opportunity to study the remote effects of the injury on the tissues. In all cases the swelling of the tissues at this time had nearly or entirely obliterated the tubular wound, the location of which was indicated by a dark discoloration, parenchymatous extravasation, remains of fluid or coagulated blood, and a limited area of edema and infiltration. These conditions served as a useful guide in following the course of the bullet. The bullet itself was usually found loose in a small cavity filled with liquid blood or blood serum, while a more extensive zone of infiltration indicated the early stage of encapsulation. I have no further doubt but what the new bullet will become encapsulated and remain harmless in the tissues, as readily or more so than the old-fashioned leaden bullet. In isolated cases late suppuration at the seat of the bullet resulted in the formation of a circumscribed abscess, a complication which aided the surgeons in locating, finding and removing the missile. It was a surprise to us all to find that in more than 10 per cent. of all the wounded, the bullet was found lodged in the tissues, a vastly greater number than we had any reason to expect. The reason for this became apparent when we began to study the condition of the bullets removed. A large proportion of the bullets removed were found deformed, showing that they were deflected bullets, which had struck a hard object or passed through a resisting medium before they reached the final object for which they were intended. The ground upon which the battle was fought is stony and covered with trees and thick underbrush, furnishing the most favorable conditions for deflection of the missiles. Some of the firing was done at a great distance, so that occasionally a spent ball was found in the soft tissues without injury of the bones. Such a bullet is shown in Fig. 1. The bullet is a nickel encased Mauser projectile, natural size, the jacket perfect, and was removed from behind the tibia about four inches above the ankle joint. It entered the calf of the leg below the popliteal space and never touched the bone. Fig. 2 represents the same kind of a bullet, the point flattened and mushroomed, removed from the head of the tibia. This bullet was probably fired from a great distance, and the deformity was produced by the bone. Figs. 3, 4, 5, represent a nickel-clad bullet very much deformed. It was found lodged in the deep tissues of the thigh about two inches from the wound of entrance, slightly overlapping the femur near the middle of the shaft. The bullet evidently struck a stone behind its point, and was deflected before it entered the tissues. It was much flattened and curved. Fig. 3 shows the convex side point of bullet and jacket perfect. Fig. 4 shows the edge and curve of the bullet. Fig. 5 represents the convex side, showing a wide rent in the jacket indicated by the dotted lines, the lead exposed between them. Figs. 6, 7, 8, illustrate

the deformity of a large caliber brass-clad bullet. As the bullet was removed from the soft tissues from a wound without bone injury, the deformity must have been caused outside of the body. The bullet is flattened on one side from a point near the tip to near the base of the lead core. Fig. 6 shows the convex side; behind the last transverse groove the lead is exposed. Fig. 7 illustrates the flattened side of the dotted line, indicating a defect in the brass jacket. Fig. 8 shows the margin of the bullet, and the location and extent of flattening. As the Spanish army is armed exclusively with the Mauser rifle, the weapon from which this bullet was fired must have been in the hands of a volunteer, or possibly a Cuban.

THE VALUE OF THE X-RAY IN MILITARY PRACTICE.

The use of the probe as a diagnostic instrument in locating bullets in modern military service has been almost entirely superseded by dissection and the employment of the X-ray. If from the nature of the injury and the symptoms presented the bullet is located in a part of the body readily and safely accessible to the knife and it is deemed advisable and expedient to remove it, this can often be done more expeditiously and with a greater degree of certainty by enlarging the track made by the bullet than by relying on the probe in finding and on the forceps in extracting the bullet. If, as is often the case, the whereabouts of the bullet is not known, its presence and exact location can be determined without any pain or any additional risks to the patient by the use of the X-ray. All of the bullets removed on board the hospital ship *Relief* were located in this manner. Dr. Gray, an expert in skiagraphy, who has charge of the scientific work of the floating hospital, has been of the greatest service to the surgeons in enabling them to locate bullets and in guiding them as to the advisability of undertaking an operation for their removal. His large collection of skiagraph pictures will also furnish a flood of new light on the effects of the small caliber bullet on the different bones of the body. Dr. Gray's work will constitute an essential and enduring corner-stone of a much-needed modern work on military

surgery. The skiagraph has enabled us to diagnosticate the existence or absence of fracture in a number of doubtful cases in which we had to depend exclusively on this diagnostic resource. In fractures in close proximity to large joints the X-ray has been of the greatest value in ascertaining whether or not the fracture extended into the joint. In one case of gunshot wound at the base of the thigh in which the bullet passed in the direction of the trochanteric portion of the femur, opinions were at variance concerning the extent of injury to the bone. Some of the surgeons made a diagnosis of fracture while others contended that there was no fracture but believed that the bullet had made a deep groove in the anterior portion of the bone and had possibly opened the capsule of the joint at the same time. The X-ray picture clearly demonstrated the absence of fracture and the existence of a deep furrow with numerous fragments on each side. The X-ray apparatus also proved of the greatest practical utility in showing the displacement of fragments in gunshot fractures of the long bones, which enabled the surgeons to resort to timely measures to prevent vicious union. The fluoroscope has greatly added to the practical value of skiagraphy. In the light of our recent experience the X-ray has become an indispensable diagnostic resource to the military surgeon in active service, and the suggestion that every chief surgeon of every army corps should be supplied with a portable apparatus and an expert to use it, must be considered a timely and urgent one.

THE WOUNDED OF THE BATTLE OF SANTIAGO.

It will be of interest to the profession to learn something definite of the nature of the wounds and their more remote results on the victims of Spanish bullets in the battle of Santiago. Two weeks have passed away since the battle. A considerable number of the wounded have died since, and many have left for the United States on the *Olivette*, *Solace* and transport ships. Among the 130 wounded now on the way to their homes on the hospital ship, *Relief*, I have selected a number of cases of more than usual interest, for the purpose of studying the effects of the small caliber bullet, immediate and remote, on the different organs and regions of the body. It is my intention to give the course of the bullets by marking on the diagrams accompanying the report of each case, the wound of entrance and exit. A study of the diagrams will show that deflection of the bullet in the body is exceptional. As a rule, the wound canal was in a perfectly straight line from one wound to the other. By following the track of the bullet it is not difficult to determine the organ or organs implicated in the injury. I shall classify the cases so as to embrace gunshot wounds of 1, the head; 2, the neck; 3, the spine; 4, the chest; 5, the abdomen; 6, the extremities.

GUNSHOT WOUNDS OF THE HEAD.

To my own knowledge, a number of gunshot wounds of the head that survived long enough to be transported to the general hospital at Siboney, died within twelve days after the receipt of the injury. In all of the cases intracranial infection was the immediate cause of death. Encephalitis and leptomenigitis constituted the fatal complications. The beginning of the intracranial inflammation was always announced by cerebral hernia, which in size was proportionate to the extent and intensity of the inflammatory process. The surgical treatment resorted to in most instances proved powerless in limiting the infection. If these cases had been studied with a little more care during life, and if postmortem examinations had been made more frequently, valuable material could have been obtained for the advancement of the as yet imperfectly developed science of cerebral localization.

Case 1.—Fred Shockley, Company D, Tenth Cavalry, wounded July 2. When injury was received the patient was lying on his abdomen with chest and head extended at the base of the ridge occupied by the enemy, which position readily

explains the unusual course of the bullet. The bullet struck the occipital base at a tangent, producing a comminuted fracture with depression; it then made a deep groove in the back of the neck and then re-entered the body on a level with the first rib to the left of the seventh cervical vertebra, passed through the chest and escaped in front through the second intercostal space, a little to the left of the mammary line (Fig. 9). Soon after the injury was received he coughed up a

Fig. 9.

small quantity of blood; no hemorrhage since or any indications of pneumothorax, pneumonia or pleuritis. The chest wounds healed by primary intention. At first had convulsions for a few moments; no loss of consciousness, but clonic spasms of both arms. At present intellect is unimpaired; has some headache and a sensation of throbbing in the head; some impairment of motion and sensation of right leg and complete loss of motion of toes of right foot; has some pain in eyes and slight dimness of vision.

Case 2.—Patrick Ward, Company I, Third Cavalry, admitted from hospital at Siboney to hospital ship, *Relief*, July 11. Injury probably received in the same manner as in Case 1. A large defect in the occipital bone marked the wound of entrance and exit in the skull, the opening enlarged by operation. The

Fig. 10.

linear wound below, and extending as far as the last cervical vertebra, was undoubtedly made in following and removing

the bullet. The cranial defect and course of bullet are outlined in Figure 10.

A cerebral hernia projects from the opening, and a deep-seated cerebral abscess was recently discovered, opened and drained. In part the hernia is covered by skin. Both parietal bones are the seat of a comminuted fracture. Mental faculties not impaired; no focal symptoms. The patient is losing strength rapidly and will soon succumb to the intra-cranial lesion.

Case 3.—Jerome Russel, Company A, Thirteenth Infantry, was wounded July 1. When brought on board the *Relief* a cerebral hernia about the size of a hen's egg was found over the sagittal suture, an inch in front of the occipital protuberance. The wound was suppurating, and digital exploration revealed a small circular opening directly in front of the occipital protuberance. This opening was evidently the wound of entrance, and by operation, had been connected with the wound of exit by a channel an inch in length and half as wide. The hernia occupied the wound of exit. A number of loose fragments of bone have been removed at different times. There is marked hemiplegia on the left side, the forearm is strongly flexed and in close contact with the chest. Sensation is not diminished; speech clear, but ideas confused; pupils react to light; incontinence of urine; extensive decubitus over sacrum; temperature 100.5 degrees F.; pulse and respiration normal.

Case 4.—B. C. Parker, Company C, Fourth Infantry, was wounded July 1. The bullet entered the left temporal region, comminuting the bone in that region extensively, and escaped over the left frontal eminence (Fig. 11). The cranial defect was increased by the removal of a number of loose fragments. There had been quite a profuse sero-purulent discharge from

Fig. 11.

the wound. The only focal symptom consists in a pricking sensation in the right foot or chest when the wound is being dressed. His mind is clear most of the time, occasionally slight confusion and wandering. The absence of cerebral hernia in this case is the surest indication that the infection is local.

GUNSHOT WOUNDS OF THE NECK.

Case 5.—Lieut. Albert Scott, Company C, Thirteenth Infantry, on July 1, while standing with his company at the

Fig. 12.

foot of a hill, during the advance on Santiago, received a wound in the neck. The bullet entered the neck on the right

side just below the inferior maxillary bone, one inch in front of the angle of the jaw. The wound of entrance is a clean cut hole about the size of a lead pencil. The course of the bullet was backward and slightly downward, emerging at the back of the neck on a level with and to the left of the fifth cervical vertebra (Fig. 12).

At the moment the injury was inflicted he felt no pain in the wound, but he experienced a sensation as if he had been grasped by the wrists and thrown violently to the ground. The wound of exit is of the same size and appearance as the wound of entrance. Very slight hemorrhage. A few minutes after receiving the injury he was carried from the firing line by members of his company, and was soon transported to the First Division Hospital, where he remained for ten days, after which he was removed in an ambulance to the hospital at Siboney, a distance of seven miles over a very rough road, and a day later was transferred to the *Relief*.

He first became aware of the existence of the wound on the way from the field to the hospital. At the time he came on board the hospital ship he was voiceless, and made constant efforts to clear his bronchial tubes of mucus. Complete paralysis of right arm and leg, and partial loss of power in left arm and leg. Respiration normal, but an almost constant spasmodic cough, no control over sphincters, involuntary passages from both bladder and bowels, great debility and profuse sweating; complains of pain all over the body. Morphia and atropin given to subdue pain. A radiograph taken by Dr. Gray shows an injury of one of the cervical vertebrae, probably the fifth. Injury seems to be to the left of the body of the bone. Has received no treatment other than complete rest and a nightly anodyne as noted above, which secures a good night's sleep, and markedly diminishes the sweating. Has regained control of the sphincters, and is able to use bed pan and urinal.

July 19.—During the past six days there has been a decided improvement in the general condition of the patient. He is brighter in appearance, he can articulate more distinctly, and there is a decided return of power in the right leg. The right hand is still absolutely powerless, but the grip of the left hand is decidedly stronger. Appetite and circulation good.

July 21.—Improvement in general condition still continues. The external wounds healed by primary intention, and the scars can only be seen on making a very careful inspection. Trional and sulphonal have been substituted for the morphia.

Case 6.—Oscar C. Buck, Company F, Second Infantry, was shot by a sharpshooter hiding in a tree, July 11. The bullet

Fig. 13.

passed through the neck from side to side. The first and only evidence the patient had that he was injured was bleeding from the throat, the hemorrhage at first being quite profuse. Stiffness of the neck and pain on movement have been the only symptoms complained of since. The bullet entered over the sterno-cleido-mastoid muscle on the left side, about two and one-half inches from the mastoid process. The wound of entrance was circular and very small; the wound of exit on the same level but about half an inch nearer the spine (Fig. 13)

Three days later a small superficial abscess formed in the wound of exit, which was evacuated by dilating the wound. Both wounds were perfectly healed July 20. Judging from the course of the bullet it is difficult to understand how the principal nerves and large vessels of the neck escaped injury. This is one of those cases that require careful watching, as a traumatic aneurysm may develop later in the throat if the bullet injured the external tunics of either of the carotid arteries.

Case 7.—Charles F. Flickinger, Company C, Fourth Infantry, was wounded July 1, while lying down. The bullet entered the left posterior cervical triangle on a level with the spinous process of the fifth cervical vertebra, midway between the spine and the posterior border of the sterno-cleido-mastoid muscle, and emerged opposite the spinous process of the

Fig. 14a.

seventh dorsal vertebra, and equidistant from that point and the posterior border of the scapula (Fig. 14a). The patient complains of severe pain in shoulders on attempting to move, but is free from any symptoms that would indicate any injury to the spinal cord. He was within 100 yards of the enemy when he was wounded.

GUNSHOT WOUNDS OF THE SPINE.

All cases of gunshot wounds of the spine in which the cord was seriously damaged have died, or will die in the near future. The immediate cause of death in such cases is either a septic leptomeningitis or sepsis and exhaustion from decubitus. Death from the first named cause takes place early as the result of infection of the wound and extension of the inflammation at the seat of the visceral injury along the meninges and surface of the spinal cord. The first case of this kind I saw was at El Caney a few days after the battle of Santiago. The patient was a Spanish prisoner. I found him lying on the bare stone floor of the village church. The bullet had entered over the center of the spine at the junction of the dorsal with the lumbar vertebrae, its course apparently being directly forward. Complete paraplegia below the seat of injury. The bladder was distended, nearly reaching the level of the umbilicus; incontinence of urine. The neck, trunk above the wound, and upper extremities rigid; fever; pulse rapid and small, countenance extremely pale. The wound was protected by a small dirty dressing, and was suppurating. I doubt not that the patient died in less than twenty-four hours after I saw him. Wounds of the spine without injury to cord were frequently attended by temporary paralysis varying greatly in degree and duration.

Case 8.—George Kelly, Company C, Seventeenth Infantry, was shot July 1, while lying in a prone position. The bullet, which was fired from a blockhouse on the summit of a hill, at a distance of about 600 yards, entered the body at a point a little below and at the middle of the right ilium, and emerged from the opposite side about three inches below the crest of the left ilium (Fig. 14b). The patient asserts that he suffered intense pain immediately after he was shot, and that he is now free from pain except when he attempts to walk. The pain

thus caused he refers to the sacro coccygeal articulation. The wounds are healed, and the absence of paralysis is the best evidence that the contents of the spinal canal escaped injury, although the bullet must have passed transversely through the first sacral vertebra.

Fig. 14b.

Case 9.—John Robinson, Company C, Twenty-fourth Infantry. The bullet entered the supraspinous fossa of left scapula and escaped from the right lumbar region, having perforated

Fig. 15.

in its long course the lung, spinal cord, diaphragm and liver

(Fig. 15). Wounds healed in ten days. Expectoration bloody, complete paraplegia. Beginning extensive decubitus over sacrum and spinous processes.

Case 10.—Otto Derr, Company A, Twenty-first Infantry, was wounded July 2. Bullet passed through the chest from side to side from the post-axillary line on the right side to a corresponding point on the opposite side, on a level with the seventh intercostal space. Complete paralysis of motion and sensation below the seat of spinal injury. The wounds healed, but life was threatened at the time from a commencing septic decubitus.

Case 11.—Lewis W. Carlisle, Company K, Seventy-first New York Volunteers, was hit by a shrapnel in the back, on a level with the third lumbar vertebra, shattering the spinous and left lateral processes of the same. The missile was removed as soon as the patient reached the Division Hospital. As profuse suppuration set in and continued, the patient was anesthetized July 18, and a number of fragments of bone removed. A large abscess cavity in the right lumbar region communicated with the wound. The cavity was drained by making a counter-opening in line with Simon's incision. Impaired sensation in the right leg was the most important local symptom in this case.

Case 12.—Charles J. Reardon, Company C, Sixteenth Infantry, was wounded by a fragment of shrapnel which struck him as he lay on his back with his shoulders raised ready to fire. The wound was directly over the spine, on a level with the fourth dorsal vertebra, the missile evidently opening the spinal canal and injuring its contents. The foreign body remains imbedded in the tissues; its location so far has not been determined. Paraplegia is complete below the level of the umbilicus. On July 18 the patient was still alive, but an extensive moist decubitus became the direct cause of death in the course of a few days.

GUNSHOT WOUNDS OF THE CHEST.

It is well known that during the Civil War men had a better chance for life when the bullet passed through

it into the chest clothing or other infective material. The number of cases of chest wounds that lived long enough to reach the hospital on the coast is still more astonishing, and what is surprising is the fact that unless the hemorrhage was

Figs. 17.

Fig. 16.

the chest than when the chest was opened and the ball removed. The same remains true now, although not to the same extent, as the small caliber bullet is less likely to carry with

severe the symptoms were mild, some of the patients being confined to bed only for a few days. All of these cases were treated on the expectant plan, i.e., by dressing the external wound or wounds in the usual manner. In no instance was the pleural cavity opened for the purpose of arresting the hemorrhage.

Case 13.—Wm. A. Cooper, Company A, Tenth Cavalry, was wounded July 1. The bullet entered an inch below the left nipple, and escaped from the body an inch below the costal arch in the mammary line (Fig. 16). It is questionable whether the bullet opened either the pleural or peritoneal cavity, as the injury was not followed by any symptoms referable to visceral

Fig. 18.

wounds of the chest or abdomen, although the course of the bullet was such as to give rise to the suspicion that either or both of these cavities might have been invaded.

Case 14.—Edward O'Flaherty, Company C, Sixteenth In-

fantry, was wounded July 2 by a 45-caliber ball from a bursting shrapnel. The projectile entered below the angle of the right scapula, passed through the lung, diaphragm and liver, lodging beneath the skin in front, between the seventh and eighth ribs (Fig. 17). Bloody expectoration for some time and slight rise in temperature.

July 12.—Temperature normal.

July 21.—Patient suffers but little inconvenience from his wound. No peritoneal or pleural effusion. General condition promises an early and complete recovery.

Case 15.—John B. Semca, Company G, Twenty-second Infantry, was wounded July 1, by a bullet which entered his back just below the angle of the left scapula, passed upward through the lung, neck and jaw and emerged through the alveolar process of the right bicuspid tooth, cutting the tongue slightly (Fig. 18). All wounds healed in a short time by primary intention. Hemoptysis profuse immediately after he was shot, and slight for the following few days. Left arm at first nearly powerless, with desquamation of skin of the hand. Function of the arm is returning gradually. In three weeks

Fig. 19.

the patient was able to sit up for a short time each day. Physical examination of the chest at this time revealed nothing abnormal.

Case 16.—Winslow Clark, Company G, First Volunteer Cavalry, was wounded July 1, by a bullet which entered the chest by first perforating the left scapula through the infraspinous fossa, three inches above the angle and a inch from the spinal border (Fig. 19). No wound of exit. The probable course of the bullet was downward and forward. Some hemoptysis and fever. No vomiting of blood. The hemothorax was quite extensive and was relieved by tapping, a week after the injury. He is now (July 22) convalescing rapidly.

Case 17.—Arthur Fairbrother, Company C, Third Cavalry, sustained a perforating gunshot wound of the chest July 1. The bullet entered the chest just below the middle of the right clavicle (Fig. 20). No wound of exit. Hemoptysis rather profuse, followed by hemothorax. Has had fever, off and on, probably malarial. Patient was admitted to the Relief July 15. Wound not completely closed. On coughing, dark fluid blood

escapes. Nearly the entire pleural cavity filled with blood. Two days later three pints of dark fluid blood were removed by tapping and siphonage. Sputum at this time still bloody.

July 22.—Patient much improved. No signs of empyema. Hemothorax diminished, but may require a second tapping.

Fig. 20.
(To be continued.)

SOCIETY PROCEEDINGS.

Chicago Ophthalmological and Otological Society.

Regular Meeting held in the Stewart Building, Oct. 11, 1898.

Dr. COLEMAN occupied the chair. He exhibited a patient on whom he had performed Mule's operation some two weeks before, and who had been wearing the artificial eye for two days. The excursion of the eye is 25 degrees up and down, and 20 degrees out. The operation was followed by very little reaction, which he ascribed to the cauterizing of the inner wall of the sclera with 95 per cent. carbolic acid, and the free use of hot water.

Dr. HOTZ had examined many cases of Mule's operation, and found that practically the only advantage was that the sulcus in the upper lid under the brow was less deep than in the ordinary enucleation; that the movements of the artificial eye over the Mule's globe were not any greater than in ordinary enucleations.

Dr. CASEY A. WOOD had done Mule's operation twice. In one case the glass ball was promptly extruded, and the other case was lost sight of, so that the result was not known. He concludes that inasmuch as the thing that seems to be desired, i. e., the prominence of the prosthesis, is the principal source of subsequent danger from pressure, there is very little in the procedure to recommend over a proper enucleation or evisceration. He referred to the aluminum frames exhibited by Bryant at the meeting of the AMERICAN MEDICAL ASSOCIATION in Denver.

CONGENITAL DISTICHIASIS.

Dr. CASEY A. WOOD presented two cases, father and daughter. Both patients exhibited absolutely normal lids apart from the supernumerary cilia. In both cases the second row is of fine white hairs, on the inner margins of both lids, few of them impinging on the cornea. The latter is free from opacity and the conjunctivæ are practically normal. Occasionally some lashes touch the corneal surface and have to be extracted. There is a plain history of both patients having exhibited the condition from early infancy.

Dr. HOTZ had seen a case in which there was a row of eyelashes coming out directly from the posterior lip of the margin, faint, fine-looking hairs protruding from the lid about one-eighth of an inch. These were easily extracted, and were found to be quite long and seemed to come from the Meibomian ducts. After being pulled a few times they ceased growing. He suggested that electrolysis be tried in Dr. Wood's cases.

Dr. WOOD stated that he had intended to try the use of nitric acid inserted into the base of the lash by means of a fine toothpick. He had found it less painful and more thorough than electrolysis.

UNUSUAL INTOLERANCE OF MYDRIATICS.

Dr. HOTZ had seen a patient, 60 years old, in August, suffering from an attack of iritis. He had a previous attack some five years before, and had used atropin at that time. He had suffered more severely from the effects of atropin than from the iritis. The symptoms during this attack were characteristic, and in spite of the previous experience Dr. Hotz dropped scopolamin in his eye several times within an hour. The pupil dilated slowly and irregularly, and the redness of the eyeball was less, but the lids were edematous and swollen. The pupil was not well dilated, and duboisin was prescribed instead of scopolamin. This had the desired effect upon the pupil, but the lids were much swollen; the conjunctiva discharged a good deal of mucus; the skin of the cheek was much puffed, and at places serum exuded. Within twenty-four hours the whole right side of the face was intensely swollen; the skin furrows were deep and eroded, and crusts of dried secretion were found everywhere. The symptoms of iritis subsided very rapidly and the duboisin was stopped. Within twenty-four hours the swelling of the face began to subside and disappeared within four days. There were no constitutional symptoms.

Dr. COLBURN—I have had almost the same experience in the case of a cataract extraction. About two years ago I operated on the left eye, and atropin produced all the symptoms that the Doctor has described. Last winter I operated on the right eye, and I used duboisin instead of the atropin, and again I had a fearful eye. The lids were distended, the nostrils closed and both eyes and the whole of the face and neck were involved, and it looked very angry. I could give no other explanation than atropin poisoning. He again had all the symptoms that the Doctor speaks of; it was the most fearful case of apparent erysipelas that I ever saw. The recovery from the operation was not interfered with: the visual result was good.

Dr. WOOD had found that there was a dermal idiosyncrasy in many patients for atropin, and that a distinct dermatitis would arise when the drug was rubbed on the skin of the arm or leg, etc.

Dr. PINCKARD had had one case where a single drop of atropin, duboisin, or hyocin brought on very marked constitutional symptoms, but not any skin symptoms. The patient was a woman about 30 years of age.

SARCOMA OF THE LID.

Dr. PINCKARD—The patient, a woman 30 years of age, I first saw in May of this year. For the past two months she had noticed a gradually increasing swelling on the lower lid just to the outer side of the punctum. It was then about the size of a large pea, the skin being a trifle reddened, and the conjunctiva a dark red color. I thought that it was a chalazion and advised its removal. On making an incision into the tumor, however, I found it to be solid, and cut out a little piece which on examination proved to be sarcoma. The question of the differential diagnosis is certainly very difficult. The only peculiarity that I noticed, and which I probably should not have noticed but for the subsequent developments, was that the border of the lid was very much raised at the site of the tumor, thus disturbing the line of the lower lid. I have not found this to be the case with chalazion, the swelling generally extending only outward or inward, and not interfering with the line of the lid border. The patient was sent to the hospital, and under ether a large V-shaped incision, beginning at the inner canthus and to the outer side of the middle of the lid and joining about an inch below the lid, was made, and the whole section removed. The caruncle, the lachrymal sac and some of the orbital tissue were also removed. The outer half of the lid was joined to the skin of the nose and healed readily by first intention, leaving but a comparatively slight scar. Some few weeks later I saw the patient for the last time, and at the site of the scar there was a suspicious looking growth, which I thought was probably the return of the sarcoma. I heard from her some two weeks ago, and she states that this had disappeared. I do not see how it is possible to make a differential diagnosis between sarcoma and chalazion before a section is made into the tumor. Certainly in this case, with the possible exception of the lid edge, there was nothing characteristic. The patient was healthy in all other respects, and no doubt this was a primary sarcoma of the lid.

Dr. WESCOTT removed from a child, early in the summer, a tumor which extended the entire length of the tarsus and covered it very completely. Some three years before, Dr. Holmes had seen the case and thought it was a chalazion, and was surprised when he cut through the skin to find a solid tumor. Dr. Holmes curetted it, but it returned very slowly, and had been growing up to the time the child was brought to Dr. Wescott. The tumor was dissected out, and the examination showed it to be a pure angioma. There was no return in five months.

DRESSINGS OF CATARACT CASES.

Dr. COLEMAN—In the last three cases I did not apply a compress bandage, simply put a gauze shade suspended by plaster on the forehead, and covered that with a papier-mache shield, and I have never had less reaction than in those cases. We all very well know that in aged people, if we tie up the eye for forty-eight hours, we may produce a conjunctivitis.

IRIDECTOMY.

Dr. COLEMAN—No one has advocated preliminary iridectomy. Landolt has written the best article I have seen of late years on cataract extraction, and he says that beyond all controversy preliminary iridectomy offers the safest prospect for recovery. All things considered, for me preliminary iridectomy affords the greatest amount of success. In reply to a question as to the use of eserine, Dr. Coleman said: I question the efficacy of it in the simple operation. I would not use eserine to prevent prolapse, but atropin. The latter, by opening the gateway, takes the pressure of the aqueous off the posterior surface of the iris and thus prevents prolapse.

Dr. HOTZ—I have never divided the operation to save the patient annoyance and nervous excitement of two operations, when I can get along with one. I do not know whether there would be anything gained by, or any greater safety in the preliminary operation.

Dr. BULSON of Fort Wayne—In discussing a paper that was presented at the recent meeting of the British Medical Association, a noted ophthalmologist cited a case in which the wound, following removal of cataract, remained open for seven or eight days. This was supposed to be due to the fact that the incision had been made wholly in corneal tissue, which in the aged repairs slowly. I have recently had under my care a similar case, in which, owing to the unruliness of the patient, the incision was made wholly in the cornea. This wound remained with escape of aqueous, for a period of five days, and notwithstanding that a small iridectomy was performed no prolapse occurred. Under pressure bandage and the stimulating effect of hot compresses the wound closed very nicely. As to the use of eserine, I do not presume to speak from a great amount of experience, as I use the drug in exceptional cases only. I believe it to be irritating in a large percentage of cases and therefore prefer to limit its use as much as possible. I have seen weak solutions produce violent irritation, and for that reason have learned to look upon all applications of eserine with considerable suspicion.

Dr. WESCOTT—I am still doing the combination and hesitate to change. I have also seen decided irritation from a half grain solution of eserine, and my ordinary prescription is an eighth or quarter of an ounce. I believe in using atropin after extraction, but I do not begin it early, and frequently have omitted it until the fourth day.

Dr. PINCKARD—When I was the house officer in the infirmary in Boston, Dr. Chandler devised an operation and operated on fifty cases with a device which was quite ingenious. He argued that the prolapse of the iris was due to the gushing forth of the aqueous, carrying the iris with it. So after doing his extraction, he cut a small piece the size of a pin-head, out of the peripheral edge of the iris. The idea is certainly ingenious and, so far as I know, was original with him. By this means he left the pupil round, and that part of the iris with the hole in it was always covered by the upper lid, and through this hole fluids could pass to the anterior chamber and thus diminish the danger of prolapse.

Dr. ROBERTSON—After operations for cataract it is desirable to have as small a pupil as possible, that is, as small a clear pupil as possible. Whether you do a simple or a modified operation, there is nearly always some secondary cataract developed, and it is desirable to have a pinhole pupil through the secondary one, for the reason that you get a greater range of accommodation. The larger your pupil the less accommodating power you have left in the eye. There is one case I recall where the man had enough accommodation to see at a distance and read with the same lens, this, not on account of any true accommodation, but by reason of the pinhole pupil, all rays of light entering the eye being practically parallel. These patients can by squinting the eye, make pressure on the globe by the lids so that the eyeball is elongated by mechanic force. This would create an artificial myopia, and in such a way give the patient an artificial accommodation. This artificial myopia can exist to an unknown amount, and we are not unwilling to concede that we might develop 3.00 D. or 5.00 D., which would be changing the diameter of the eye only 1.75 mm. I do not think it makes much difference when you fit the patient after extraction, as some will wear the same correction always, while others require changing often.

Dr. WESTCOTT—I had one traumatic case of cataract in a

boy where I did a very small iridectomy and got vision of 20/40 with the proper lens. With the same lens the boy could read the smallest type. I ascribe this power to the very small pupil.

DISCUSSION ON CAPSULOTOMY.

Dr. COLEMAN—In doing capsulotomy with the ordinary capsule I should not be tempted to use a forceps, but in a tough capsule I am very decidedly in favor of using the forceps, and in the few instances in which I have had occasion to use it, the result has been most satisfactory. I do not see why some of the text-books should recommend removing the capsule subsequently to removing the lens. This seems to me very dangerous.

Dr. HOTZ—My experience is somewhat unique, but in all my extractions I never came across any capsule that I could not cut with a cystitome. If I should encounter one that the cystitome should fail to cut, I should rather remove the cataract in the capsule *à la Pagenstecher*.

DISCUSSION ON SECONDARY OPERATION.

Dr. HOTZ—I dislike to do secondary operations, and if a patient has anywhere near satisfactory vision I do not perform them for the sake of getting better vision. I can not understand how anybody can advocate them so persistently as if they were the simplest and most harmless operations. No matter what instrument may be used, the mechanic action certainly is not so much cutting as tearing. We have very little chance to cut a capsule, and I have found that the membrane will yield before the knife until it tears. If the membrane is very thin, no serious reaction follows; but if at all thick the reaction is severe. In cases of dense membrane, I am in the habit of using two fine sharp hooks introduced through the cornea, and tearing the capsule in the center. As the traction of one hook resists the other, there is no dragging on the ciliary region. Even in cases of thin membrane, I have seen violent reaction follow secondary operation and have been able to demonstrate the presence of a small thread of vitreous in the hole in the capsule.

Dr. COLEMAN—I most heartily agree with what Dr. Hotz has said, and I can not understand why some operators make so light of a secondary operation. While the knife needle in my hands has been followed by unfortunate results, I have quite frequently operated on tough membranes with the de Wecker's scissors, and always with gratifying success, a good pupil having been secured and with very little reaction.

Dr. PINCKARD—I have often seen the operation referred to by Dr. Hotz, done in Boston, particularly by Dr. Jeffries. Usually but one hook was used, the other point of traction being a Bowman needle. The needle was passed through the cornea and into the center of the capsule, and then a hook introduced from the opposite side and a tear made with the needle as a point of resistance.

Dr. WESTCOTT I have accomplished the same thing by introducing two needles on opposite sides of the cornea into the center of the capsule and thus tearing the capsule.

DISCUSSION OF REFRACTION OF CATARACT CASES.

Dr. WESTCOTT—We have to be guided in these matters very largely by the means of our patients. A good many, especially those from the country, are very anxious, for more than one reason, to return as soon as possible, and they all want some sort of a glass when they go home. I have been in the habit of measuring the refraction carefully between the end of the second week and the beginning of the fourth week, and have given the patient the spheric lens which gave him the best vision. I have asked some of these patients to come back in three or four months, and I know that in more than one instance I have been able to give a permanent glass at the end of sixty days, that was still the best glass I could find in a year. In other cases, one of which I have in mind now, I found a very decided change at the end of a year. I extracted a cataract up in Minnesota last September. I left the patient two or three weeks after the extraction, and he accepted then a +9 sphere with a +4 cylinder. I gave him a +9 to wear and he was perfectly satisfied, except that he could not read. This year I found the patient had even less vision, 20/100, with the best correction which I could give him, which was a +12 sphere and a +4 cylinder, at which he was very much surprised. In the dark room I found that the posterior capsule was thrown into fine vertical folds. The anterior capsule was out of the way entirely. I advised needling, and performed the operation on the following day. After a week's time, during which there was absolutely no reaction, the patient accepted the same correction, but got 20/30 vision, and was able to read his newspaper. If we could see all our cataract patients once a month for a year, we could decide this quee-

tion, but otherwise I do not see how we can. I ask my patients to stay in town a month, when they come from outside for cataract extraction. Then I ask them to come back in three months, and then again in six months, if the glasses are not perfectly satisfactory for all purposes, and in that way I have given some patients better satisfaction, I am sure, than I could if I set any definite time for giving final correction.

Chicago Medical Society.

Regular Meeting Oct. 26, 1898.

Dr. J. C. HOAG, first vice-president, occupied the chair.

Dr. HAROLD N. MOYER presented a paper to the meeting, entitled

DUMBNESS OR CONGENITAL APHASIA OF A FAMILY TYPE WITHOUT DEAFNESS OR OBVIOUS MENTAL DEFECT.

He described the case of a boy, 9 years of age, who was otherwise bright and intelligent, who understood all that was said to him, but who had spoken only the one word "mamma" until his eighth year. It could not be learned at what time of life he acquired this word. Inquiry into the family history showed that the father was totally aphasic until 6 years of age, and that two brothers and one sister were similarly affected, none of the latter speaking until 4 years of age. A paternal uncle and cousin were affected with lalling all their lives. The two brothers of the patient grew up and occupied positions in life above that of the parents. The father and two grown sons had an excellent command of language, free from all defects of articulation.

He referred to several classic examples of sudden speech in those who had been previously dumb: the son of Croesus and the Samian athlete.

The extreme rarity of the affection was shown, an examination of 4485 mutes showing this condition in only seven, and many of these were more defective as to general mentality than those which he described. The explanation of Bastian was referred to, in which he claims that language is to a certain extent instinctive, and in these cases there is some barrier to the emission of speech; under the influence of a strong emotion that is swept aside and speech follows. One of the cases coming under his observation did not speak until the fourth year. Then speech suddenly began, at first imperfect, but in three months he spoke as well as the average child of his age.

Dr. CHARLES H. MILLER presented a paper on

THE PROTEOLYTIC VALUE OF MALT.

After briefly reviewing standard authorities and giving the results of experimentation, he draws the following deductions:

1. Properly prepared, light-colored, semiliquid extracts of malt, possessing strong amylolytic power, have also positive proteolytic value, though decidedly less marked than the better known ferments, pepsin and trypsin.

2. The reaction of the media bears an important relation to the results obtained. This influence is believed to be as follows in sequence of greater activity: 2 per cent. lactic acid; 5 per cent. sodium carbonate; 6 per cent. sodium chlorid (neutral), and 5 per cent. hydrochloric acid.

3. Judging from these experiments, and in the proportions employed, the proteolytic power of malt extracts is about 5 per cent. that of pepsin or pancreation.

4. The dry diastase preparations were not found to possess proteolytic power. The best results were obtained by a freshly prepared extract of malt just before use.

Good malt extract is a valuable food, concentrated and immediately assimilable. It is capable of immediately converting enormous quantities of non-diffusible carbohydrate food starches into soluble dextrin or maltose forms, ready for the use of the body. It is in the amounts commonly administered, capable of largely converting the proteids of an ordinary meal into diffusible peptones. It is distinctively a pleasant medicine, and one readily combined with practically all other remedies, often completely obscuring their disagreeable properties. Malt extract is a first class remedy, and the simplest rules of combination render it doubly satisfactory to use. Regarding administration: it should be given just before or with the meal, and can always be advantageously combined with lactic acid to pleasant tartness, other medicines not interfering.

Dr. DANIEL R. BROWER offered the following preamble and resolutions, which were adopted:

WHEREAS, the members of the Chicago Medical Society regard with deep concern the demoralizing and unprofessional conduct of Prof. Emil Behring in lending his aid to the Dye-Werke (Farbwerke) of Hoechst-on-the-Main, Germany, to the securing of a patent on diphtheria antitoxin; and

WHEREAS, the behavior of Professor Behring is derogatory

to the professional character, in conflict with the ancient traditions of medicine, and in sorry contrast with the example of Simpson, Pasteur, Lister, Helmholtz and a host of other illustrious physicians; and

WHEREAS, the history of recent biologic science clearly exhibits the important contributions made to the development and establishment of serum therapy by a number of Behring's predecessors and contemporaries, whose credit he seeks to appropriate; and

WHEREAS, antitoxin of the highest grade, possessing a potency and efficacy far greater than that of the Behring product, has for years been supplied in the American market, at reasonable prices, therefore be it

Resolved, by the Chicago Medical Society, that Professor Behring's conduct is unworthy of his scientific reputation; that his claims to priority in the discovery of antitoxin serum are unfounded; and that the granting of his patent, after five successive rejections by the examiner, was unjust, erroneous and contrary to public policy;

Resolved, that it is the duty of every member of the Chicago Medical Society to renounce the use of the Behring serum, and that the American manufacturers who purpose contesting the patent in the courts are entitled to the moral and substantial support of every American practitioner;

Resolved, that the secretary be requested to send copies of these resolutions to the leading medical journals of the United States, thus giving them a wide publicity.

San Francisco Academy of Medicine.

October Meeting.

Dr. CAGLIERI read a carefully prepared paper on a case of

ACTINOMYCOSIS OF THE LUNG,

which was of considerable interest, as it presented some rather novel features and as these cases seem to be somewhat rare. The patient was a woman 30 years of age, married and having one child. The history, as obtained by the Doctor when he first saw the case, some little time after the onset of the disease, was as follows: The woman was of very slender build and extremely nervous; there was no family history of any nervous, tubercular or specific trouble. She lived in a comfortable home, well provided with all the necessities and many of the luxuries of life. The illness had commenced with a sudden consolidation of the middle and lower lobes of the right lung, accompanied with a temperature of 105 degrees; after ten days this seemed to slowly resolve, and the temperature dropped to 101 degrees, with rises in the mornings. No further change had occurred up to the time when the case was first seen by Dr. Caglieri, about a month from the first onset. When thus seen she was very much wasted; respirations were rapid and shallow, the left chest having less motion than the right; the breasts were soft, smooth and flabby; the lower half of the right chest was the site of a very perceptible fremitus. On the right side was found an area of dulness extending as high as the sixth rib in the median line, and as high as the fourth rib on the side. Other portions of the right and the whole of the left lung were hyperresonant. On auscultation a large variety of râles could be detected—puerile, bronchial, and moist—and vocal resonance was reduced. The heart sounds were weak, but otherwise practically normal. The abdomen presented no abnormality. A diagnosis was made of a sacculated right pleural effusion, and it was decided to at once examine with the exploring needle. The needle located, on somewhat deep puncture, thick, creamy pus. On the following day, when it was attempted to aspirate and wash out the right pleural cavity, it was found that no pus could be drawn into the bottle, no matter where the needle was introduced and no matter how deep the puncture. At this time she was suffering from an almost continuous cough, with more or less bloody expectoration and night sweats. The sputum was carefully examined, but no tubercle bacilli could be found. A few days later the exploring needle was again used, directed in various points and rather deep; again a small amount of thick pus was found, and it was decided that there were a number of small sacs of pus at various points, held between the lung and the chest wall. Shortly after the last exploratory operation an area of inflammatory congestion appeared on the right breast, at about the region of the fifth to the seventh ribs. This was edematous, congested and painful on pressure, and it was thought that there might be some periostitis, resulting from infection from the exploring needle. An incision along the rib showed the presence of some periostitis; the lesion was then scraped and packed. The inflammatory process seemed to be but little checked, however, and very soon other foci appeared, ulcera-

tion set in and many small yellow granulations made their appearance at the site of the inflammatory trouble. It was now suspected to be a case of actinomycosis, and slides were made from the pus of the ulcerating areas, and also of the sputum. Nothing was evident in the sputum, but in the pus were found numbers of rod-like bodies, easily identified as the actinomycosis. The patient was then placed on iodine and Fowler's solution, and intravenous injections of corrosive sublimate were about to be tried, when the patient changed her doctor. She was not seen again for some weeks, when she once more sent for Dr. Caglieri, who found her condition much worse; she had been operated upon a number of times for "lupus," but without any benefit. There were ten or twelve sinuses when she was seen again; she was very weak, and the expectoration of bloody sputum was almost continuous. She rapidly sank and died two weeks later. No postmortem could be held. The Doctor then took up the clinical features of the case, and suggested that there were four conditions to be considered:

1. Was the pneumonia the primary condition, on which through exhaustion, the actinomycosis had become engrafted?
2. Was the actinomycosis a primary condition, which had simply been aggravated by the pneumonia?
3. Had the actinomycosis produced a consolidation, which resembled a true pneumonia?

He then cited a case reported by Dr. Hodenpyle in the *Medical Record* during 1890, in which the clinical symptoms were practically identical with those in his own case, and in which a postmortem had been made; in his opinion the postmortem changes in the case he had just reported would have been found to have been the same as in the case reported by Dr. Hodenpyle.

Dr. KENGLER mentioned a case he had recently seen in which there had been very much the same history, except that the symptoms all pointed to an incurable involvement of the liver, but on postmortem examination he had found a very large abscess of the liver, with also a large amount of pus at different points in the pleura. No slides nor cultures had been made, so that it was impossible to say that it was really a case of actinomycosis, but in his opinion this was the diagnosis. Shortly before death lung symptoms made their appearance, and there was quite an area of solidification on the right side of the chest.

Dr. TAIT objected to the Doctor's making the comparison of the postmortem changes in his case and another case, when he could not say that the condition in his own case was thus and so. He also suggests that there might have been enlargement of the glands, or at any rate infection of them, even though they were not very evident, and that infection did often involve the glands in these cases. He also thought the pus drawn at first should have been examined, and the possibility of the real trouble suspected. He mentioned the value of the examination of all such cases by means of the X-rays, as such examination tended to elucidate the diagnosis very materially by showing whether the pus was in the lung, or in a large pleural sac, or in a number of small sacs.

Dr. CAGLEIRI, in closing the discussion, said that he did not believe it all necessary to examine every case of pleural effusion by means of the X-rays, and that he doubted the actual value of such examination, though he had not employed it. As to the postmortem condition being assumed to be the same as the case reported by Dr. Hodenpyle, he had read reports of four other cases presenting the same clinical features, and they had a remarkable correspondence in the matter of the postmortem condition; he, therefore, thought it not improbable that his case was subject to the same or similar changes, and so mentioned what he thought would probably have been found if such examination had been made. He did not agree with Dr. Tait in the matter of the enlargement of the glands, for he was quite sure that in the case just reported there was no such enlargement, and he also thought there had been no infection, though of this he could not be sure. This case was peculiar, in that it began acutely and so continued, and that at first there was nothing to point in any way to any condition other than a pneumonia, with subsequent formation of pus in the pleural cavity.

Mr. GILLIHAN, a senior student in the Medical Department of the University of California, presented some beautifully preserved and mounted specimens, and described the formula and method of making the preservative mixture. The formula had been suggested to the chief of the University Clinic Laboratory by Dr. Philip King Brown. It is as follows:

GELATIN-FORMAL FLUID.

Soak the gelatin in distilled water for twenty-four hours; pour off the water and then warm the gelatin over a water bath

until fluid; then cook, of the gelatin (fluid), 1 part; distilled water, 1 part; glycerin, 2 parts; this should be cooked until the whole is well mixed, stirring all the time with a glass rod. It should then be strained through a flannel cloth and allowed to cool somewhat, when enough 40 per cent. formalin is added to make a 4 per cent. solution. Into this solution, while at about 37 degrees C., the specimens should be placed. Mr. Gillihan said that he had found some trouble with the formula as given, and more trouble with the gelatin as found in the market; owing to bad gelatin a number of specimens had turned milky white a short time after they were put up. He had experimented with all the varieties of gelatin which the San Francisco market afforded, and had found that Knox's gelatin was the one which gave the most satisfactory results. He said also that it was very difficult to make the proper measurements when the solutions were hot, so he had calculated and experimented until he had arrived at the proper quantities to be taken before assembling. The formula as he now uses it, is as follows: Gelatin (dry) 50 gm.; glycerin, 450 gm.; distilled water, 400 gm.; formalin (40 per cent.) 100 gm. The formalin must be very carefully added at the last, or the whole will coagulate. He had found that the best method of making permanent specimens was to use a Petrie dish of the requisite size, making the seal between the dish and the cover by means of a mixture of paraffin and resin, equal parts, which could be poured into the space between dish and cover while hot. Among the specimens shown was one which had been exposed to sunlight every day for two months; it was of a brain section, and had not faded at all.

Dr. F. DUDLEY TAIT exhibited a specimen of a cancerous breast which he had removed by Kocher's operation, and spoke of the relative values of Halstead's and Kocher's operations for amputation of the breast in cancer. He was quite of the opinion that Kocher's operation was very much superior to that of Halstead, and for many reasons. It made the operation much more simple, cleanly, and less liable to cause inoculation by means of carrying infection to uninfected tissues. It was also less bloody; he had operated in one case where only five ligatures had to be tied in the course of the operation. This question was discussed by Drs. Sherman and Brunn.

Mississippi Valley Medical Association.

Twenty-fourth Annual Meeting, held at Nashville, Tenn.,

Oct. 11-16, 1898.

Concluded from page 1114.

THIRD DAY—AFTERNOON SESSION.

Dr. ALEX. C. WIENER of Chicago read a paper on

SURGICAL TREATMENT OF PARALYSIS IN CHILDREN.

A clear distinction should be made in diagnosis as well as treatment between cerebral and spinal paralysis. A common symptom in both diseases is paralysis, and yet there is great difference between the two affections. In spastic paralysis one group of muscles becomes rigid and overpowers its opponents, rendering them overstretched and useless, but still their innervation is by no means disturbed. In spinal paralysis there is a true degeneration of the lower neuron and the dependent muscular groups. This being borne in mind, the treatment is to equalize the balance between the spastic and the overstretched muscular group by lengthening the rigid muscles. This is done either by tenotomy, resection of tendons or loosening the attachments of the muscles from the bone, as is done in a spastic condition of the adductor muscles of the pelvis. The after-treatment consists mainly in not allowing the extremity to leave its over-corrected position too soon, and in strengthening the functionally weakened opponents by massage, baths and electricity. Apparatus in these cases is utterly useless and should be entirely discarded. Any other peripheral cause of reflex irritation, as phimosis, occlusion of the prepuce, or of the clitoris, is to be removed. In anterior poliomyelitis we have to deal with a true paralysis of certain muscular groups. This may be overcome by apparatus which supplants the paralyzed muscles, or by operative procedure. This consists of dividing the belly of an active muscle up to the place of its insertion and sewing the corresponding part of the tendon into the cleft of the tendon which belongs to the paralyzed muscle. The inactive muscle is supplied with the vigor of the innervated muscle, taking care, as Milliken has pointed out, that the sheath of the tendon is preserved. By this artificial change in the arrangement of muscles the function of one muscle is transmitted to another. There is taking place an alteration of the reflex activity in the nerve centers of the muscles; hence the

importance of the function of the extremity is by no means a mere mechanical act.

Dr. JOSEPH RILUS EASTMAN of Indianapolis read a paper on

THE DIAGNOSIS OF GONORRHEA IN WOMEN.

The diagnosis of this affection in women is comparatively easy, even without the microscope. With a history of impure coitus, free purulent secretion from the vulva, vagina and urethra; intertrigo burning on micturition and vesical tenesmus, the diagnosis is not far to seek. Upon inspection one usually detects a discharge of tenacious pus, or greenish or yellowish streaks upon the linen may alone be in evidence. The symptoms of gonorrhea in women were dwelt upon at great length.

The gonococcus grows upon flat epithelium. A comprehensive examination of the discharge is not complete until the secretions of the urethra, Skene's lacunae, the glands of Bartholin, the vagina and cervix, have been searched through; and in chronic cases several preparations should be made from each of these. To secure unmixed gonorrheal pus from the cervix uteri, care should be taken that the platinum wire does not come in contact with the vagina. It is best first to rinse, and then dry the vagina with cotton to free it from mucus.

It will be concluded after many examinations for gonococci, that the urethra is the seat of predilection of gonorrhea in women, and that the vulvitis and vaginitis are secondary, being caused by the bathing of these parts with the discharge from the urethra and cervix. The diagnosis of acute gonorrhea may be made by contemplation of the clinical phenomena alone. For example, if acute urethritis be present, it is almost certain that the gonococcus is to blame. Observation for a few days will establish the diagnosis beyond conjecture, since the symptoms of non-specific urethritis will disappear rapidly. In chronic gonorrhea too much dependence upon clinical manifestations is hazardous. Condylomata are often present, but appear also often independently of gonorrhea. Débris laden discharge from the vulvo-vaginal glands is usually an expression of old gonorrhea, but other germs, as the staphylococcus aureus and saprophytic forms, may occasion just such discharge. Among the more common indications of chronic gonorrhea are the maculae gonorrhoeae of Sanger; red papules about the openings of the vulvo-vaginal glands; sclerotic inflammation of these glands, and scars and erosions in the vulva. All these conditions may be caused by other germs than gonococci. Here, as in acute gonorrhea, the most reliable indication is the urethritis.

Dr. A. M. CARLTON of Louisville read a paper on

POSTERIOR DISPLACEMENTS OF THE UTERUS,

in which he dealt with the subject from a clinical standpoint. He discussed the causes, symptoms and diagnosis of these displacements. Treatment should be divided into measures which correct the cause and methods of support by suturing and shortening the round ligaments. Sometimes it is necessary to employ both methods in the same individual in order to make the result durable. In the first category are to be included thorough curettage; repair of cervical lacerations, if present; perineorrhaphy and restoration of the pelvic floor; tonics, laxatives, and rest. These methods, if carried out successfully, will ultimately relieve the vast majority of posterior displacements. They are not so dramatic or sudden in their relief as ventrofixation and Alexander's operation, but are more in accord with rational ideas. In order to succeed they require time—six to eight months—for the structures to resume their normal tone. They also usually require to be supplemented for some weeks or months following their performance by anterior and posterior tamponnage, or a well-fitting pessary to hold the uterus in position until the repaired parts regain their strength. It is irrational surgery to use any form of support until existing causes have been as far as possible removed.

As between ventrofixation, and Alexander's operation, preference should be given the latter, if no accompanying disease is suspected. Where such disease exists, the operation of ventrofixation should be practised, as is given opportunity for inspection and correction of the pelvic disease. It is the best operation in all cases of adherent uteri.

Dr. A. H. CORDIER of Kansas City, Mo., followed with a paper entitled

SOME PHASES OF INTESTINAL OBSTRUCTION.

The causes of this condition are many and varied. Modern methods of diagnosis in skilled hands have led to the saving of many lives, which, heretofore, would have been lost by delay in resorting to the proper treatment. While the diagnosis of intestinal obstruction can usually be made early, there are some cases in which the pathologic manifestations are so insidious or vague that their detection requires time and much clinical

analysis. The symptoms of intestinal obstruction were thoroughly outlined. He said the falsehoods uttered by pain and the truths untold by opium have been very expensive to human life in the management of intestinal obstruction. Surgical treatment for the relief of this condition should be resorted to early. It should be thorough and quick. No protracted delays or chronic surgery should enter into the management of an acute intestinal strangulation, as these cases stand prolonged anesthesia and slow surgery badly.

Dr. F. F. LAWRENCE of Columbus, Ohio, followed with a contribution entitled "Essentials to Success in Abdominal Surgery."

Dr. BAYARD HOLMES of Chicago read a paper entitled "The Surgical Treatment of Exophthalmic Goiter." He said the surgical treatment is based on the theory that in this disease the direct morbid factor is an increase in the normal excretion of the thyroid gland. He gave a synopsis of the physiology and pathology and an outline of the embryology of the thyroid, after which he reported a case upon which he had operated, which was a very powerful argument in favor of surgery in dealing with this affection.

Dr. J. S. NOWLIN of Shelbyville, Tenn., contributed an article on "Some Forms of Gangrene and their Treatment." Gangrene means death of a part, and is applied to the soft tissues. The blood is always involved in this disease. If the blood is performing its functions, there can be no local death. The blood-channels being destroyed, gangrene necessarily follows. Gangrene appears sometimes suddenly after injuries to the spinal cord. A normal functional activity in the blood prevents the first step in the process of inflammation. Simple endarteritis may be the cause of gangrene; an inflamed artery is then surcharged with blood, stasis results, coagulation takes place, the lumen is destroyed to a certain extent and gangrene results. Sepsis is doubtless a most frequent cause of gangrene in the extremities. In traumatic gangrene the surgeon should look out for sepsis. If there be a simple endarteritis with tissue formation, amputation should be performed at the first evidence of failing vitality.

FOURTH DAY—MORNING SESSION.

Dr. A. H. OSNESS of Dayton contributed a paper on "Diphtheria and its Logical Treatment." He said the pathologic process in diphtheria is caused by the serum albumin at the point of infection becoming moderated from incorporation with the specific virus. It is then repudiated by the blood-stream and exudes into the neighboring tissues, where it, plus necrotic cells and fibrin, forms the pseudo membrane, that is, a congenial nidus for the Klebs-Loeffler bacillus. The intoxication of the system depends upon the energy of the lymphatics upon which devolves the removal of the exudate. In the treatment the use of antitoxin serum offers the risk of over-toxicity from additional toxin, or systemic impairment from invalidism of the centers; while monosulphide of calcium has been given in three-quarter-grain doses every half hour for a period of thirty-six hours to children with the best of results. Water should be taken internally quite freely to help elimination of the toxin, local swabbing being resorted to as well, with a mixture such as the physician deems necessary.

Dr. WILLIAM K. JAKES of Chicago followed with an excellent contribution on "The Early Diagnosis of Diphtheria," which appeared in full in the JOURNAL of October 29, p. 1046.

Dr. H. W. WHITTAKER of Columbus read a paper on "Pichi." In Chili, South America, pichi is found growing as a shrub in abundance. No doubt the active principle of the drug resides in the balsamic resin, but chemic examinations have so far been unsatisfactory in determining its chemic composition. The annoying symptoms of chronic cystitis with enlarged prostate yield to the action of pichi, as was illustrated by the citation of a case. Cystitis complicating specific urethral infection, involving the prostatic urethra, is a combination which under favorable circumstances does not readily respond to treatment, and yet under the influence of this drug the conditions become more tolerable. This remedy is indicated in all the various forms of diseases of the liver. In gall-stones, pichi has proven a valuable remedy in assisting the secretion of bile and theoretically aiding the discharge of the stones. Uric acid formations rapidly disappear from the urine under the corrective influence of this remedy and the general condition of the patient improves.

Dr. I. HENRY CARSTENS of Detroit reported a case of rupture of the body of the uterus during confinement.

Dr. A. RAVOGLI of Cincinnati presented "A Few Practical Points in the Treatment of Posterior Urethritis." The author recapitulated the principles of the treatment for this disease as: 1, irrigations with the Janet method in a recent case of gonorrhea will in many cases prevent posterior urethritis; 2, irriga-

tion with the recurrent catheter, with permanganate of potassium, followed by injections of protargol, will cure in a relatively short time a case of subacute posterior urethritis without complications; 3, when chronic posterior urethritis lasts for a long time, and has caused infiltration of the submucous tissues, then the application of a sound with ichthylol salve gives the best results.

Dr. F. E. KELLY of Lamoille, Ill., read a paper on "Varicocele." The author outlined the operation for radical cure and the indications for its performance. He considers Bennett's operation of resection of the veins and shortening of the spermatic cord the ideal radical procedure, which he described in detail.

Dr. R. A. BATE of Louisville read a paper on "The Arthritic Diathesis." The term "diathesis" is applied to an inherited predisposition to altered nutrition. He assumed in diathesis an inability on the part of the cells to produce oxidation. He mentioned the diseases generally conceded to be dependent upon the arthritic diathesis. He has experienced favorable results from antilitheic remedies in glycosuria, nasal and bronchial asthma, lithiasis, albuminuria, obesity, eczema, parosis, rheumatism, angina pectoris, recurrent typhilitis, vertigo, biliousness, dyspepsia, neuralgia and migraine.

Dr. ALBERT E. STERNE of Indianapolis contributed a paper entitled "A Trilogy of Diseases: Acute Articular Rheumatism, Endocarditis and Chorea." He advanced considerations concerning the nature of these three affections and of the connection of chorea with manifestly infectious disease, namely, acute articular rheumatism. A case was reported in point. While he could report several instances of chorea associated with both arthritis and heart lesions, this is the only case known to him where the sequence of this trilogy seemed distinctly connected with a suppurating injury, following a fairly incontestable portal to the invasion of the ordinary pus microbes to the system. If it be admitted that valvular disease is mainly rheumatic, or at least infectious in character, then the list of cases of chorea connected with the diathesis becomes much greater, inasmuch as from 25 to 50 per cent. (Osler) of cardiac patients give a history of chorea. Looking at the question impartially, it seems almost imperative to assume an intimate relationship between the three diseases.

The following preamble and resolutions were offered and unanimously adopted:

WHEREAS, The general public, the medical profession and the drug trade of the United States have long suffered extortion at the hands of foreign manufacturers of synthetic remedies; and

WHEREAS, Our lax and indulgent patent laws bestow a triple monopoly upon the process, the composition and the name of chemically products for medicinal use, thus excluding every possibility of a healthy competition; and

WHEREAS, The same evil has been recently disclosed in the domain of biologic medicine by the patent granted Prof. Emil Behring and the Hoechst Farbwerke on anti-diphtheritic serum, a patent which could not be obtained in Germany, France, England, or Canada; therefore be it

Resolved, By the Mississippi Valley Medical Association that the seal of its condemnation be placed upon the unethical and unprofessional conduct of Professor Behring; that it is the duty of every member to renounce the use of the Behring serum; and that the American manufacturers who purpose contesting the patent in the courts are entitled to the moral and substantial support of every American practitioner;

Resolved, That an earnest appeal be made to the members of the commission on the revision of our patent and trademark laws, appointed by President McKinley, and their assistance invoked for the modification of existing laws and the suppression of prevailing abuses;

Resolved, That a copy of these resolutions be sent to every medical journal in the United States and to the members of said commission, as follows: Hon. Arthur P. Greeley, assistant commissioner of patents, Washington, D. C.; Hon. Peter Grosecup, Chicago, and Mr. Francis Forbes, New York City;

Resolved, That the members of this Society be urged to write their Congressional representatives at Washington and bespeak their support of any measures of relief ultimately proposed by the commission.

The following officers were elected for the ensuing year:

President—Dr. Duncan Eve, Nashville.

First Vice-President—Dr. A. J. Ochener, Chicago.

Second Vice-President—Dr. J. C. Morfit, St. Louis.

Secretary—Dr. Henry E. Tuley, Louisville, re-elected.

Treasurer—Dr. Dudley S. Reynolds, Louisville, re-elected.

Chicago was selected as the place for holding the next meeting, the time of which is to be fixed by the committee of arrangements and the executive officers.

Seventieth Congress of German Naturalists and Physicians.

These congresses are always well attended, and prove an instructive intercommunication of ideas in various domains of science. It was held this year at Düsseldorf, with over 2300 registered.

Professor KLEIN delivered the first address, on the necessity of courses in the universities to complete the instruction afforded by the technical and medical colleges, for those who wish to acquire a special knowledge beyond the average required for the ordinary career, mentioning as an instance and a distinct progress, the advanced course in physical processes on the largest scale, at the Göttingen University, illustrated by heating appliances, dynamos, etc., supplied by private initiative, a company formed of prominent engineers and firms, who supplement their gift with their advice.

Professor TILLMAN'S address on "One Hundred Years in Surgery," pointed out the lines for the further development of surgery in the scientific deepening of surgical pathology and the closest co-operation with the other branches of medicine, especially internal.

V. NOORDEN recommended Trousseau's forgotten treatment of asthma bronchiale with atropin, commencing with .5 and increasing progressively to 4 milligrams and then decreasing. No secondary effects have been observed and this treatment wards off a recurrence of the affection for a long while, although it has little effect on an existing attack.

BLUM considers the thyroid gland a deintoxicant. He affirms that the iodine found in the gland is used to neutralize toxins. The toxic substances in the blood which normally are taken up and rendered inoffensive by the thyroid pass into the circulation after removal of the gland, and cause not only clinical but pathologic-anatomic symptoms of irritation in the central nervous system, which correspond in every way to the disturbances caused by intoxications. The toxin is therefore a nerve-toxin, which is generated normally in the organism, and normally is arrested by the thyroid and deprived of its toxicity.

DRESER described the effects of heroin, a new morphin derivative, which is tenfold as effective as codein in rendering the breathing slower, while only one-tenth as toxic. He has found it very valuable as a cough medicine; dose 0.01. It also doubles the volume and strength of the inspiration and favors the lungs by relaxing the muscles throughout the body.

W. SCHMIDT described the simple technic of his fermentation test of the functions of the intestines, which sometimes gives the clue to disturbances of the small intestine in the absence of all other symptoms. It is based on the principle of the tests of the X-deficit in the gastric juice by after-digestion, showing which of the unused remains of the food are to be considered as pathologic appearances and which as normal losses.

SCHULTZE'S surgical treatment of lupus of the face covers the defect with whole flaps taken from the neck after the patches have been excised. If the mucous membrane of the nose is involved, he first removes the skin and leaves the membrane till a month later. To limit the plastic operation as much as possible he detaches the nostrils from the back of the nose and extends them until entirely healed, when he sutures them in place again. He waits from six to twelve months after extirpation of the lupus patches before he reconstructs a total defect of the nose or lips. In 57 cases he has had eight relapses around the edges.

ENGEL and ALBUS reported successful treatment of lupus with the Roentgen ray.

KRABBEL recommends a metal shield to protect the sound skin.

FRANK, in the discussion of Cesarean section, observed that the danger of hemorrhage depends less upon the manner of incision than upon the location of the placenta, although the danger of infection is greater, the more the uterus is handled.

EVERKE stated that the results of Cesarean section would not be more unfavorable than the results of perforation, if the cases were seen earlier, and attributed his 11 per cent. mortality from sepsis in thirty-five cases to the fact that all cases had been repeatedly examined before reaching him. He warned against the danger of operating before actual labor had commenced. In his three cases of sepsis after conservative section, he found the uterine wound gaping. The main point therefore is a perfect suture of the uterus. To accomplish this he now applies inner, decidual threads tied on the side of the uterus, with additional, outer threads, deep and superficial, tied toward the peritoneal cavity. Five of his conservatively treated patients have borne children since.

ESCHERICH discussed the significance of bacteria in the etiology of gastro-intestinal disturbances of infants, stating that wherever there was evident infection and contagion a chain

coccus was invariably found in the feces and vomit, which Heubner confirmed, and after death, in the viscera, especially the lungs. He found that in the disturbances unmistakably caused by the bacillus coli, there was a serum reaction, as in typhus, but only with bacilli cultivated from the same individual. He has found disinfection of the intestines unreliable, but has derived great benefit from dietetic measures that influenced the bacterial vegetation by altering the food stratum. These infective affections require more care than hitherto supposed, to avoid contact infection, and keep them apart from suppurating wounds and septic matters, as in the prophylaxis of puerperal fever.

M. MENDELSON delivered an able address on "Nursing the Sick." He ranks it as "a science with an exceptionally large number of means at its disposal to accomplish its ends," and, with scientifically applied stimuli, affect the functions of the organism and control blood-pressure, perspiration, respiration, sleep, etc. Further research in regard to therapeutically effective stimuli should be accompanied with scientific study of their application by the nurse.

GOLDBERG related the extremely beneficial results he had attained in urogenital tuberculosis, with 1.0 to 3.0 ichthyol *per diem* in a fluid form. Not only did the general health improve, but all the local phenomena were favorably affected.

SCHEDE added three and KRABEL one, to the eight cases on record (Graf) of permanent recovery after an operation to relieve severe Jacksonian epilepsy. Success is only probable when all the symptoms are present.

B. BENDIX reported his investigation of 140 women to determine the effect of menstruation on the lacteal secretion. He found that the menses returned in 60 per cent. during the nursing period, usually commencing six to eight weeks postpartum, but they did not affect the milk, or so slightly as to be unimportant in most cases, and hence that, everything else being favorable, there is no need to reject a wet-nurse on this account. Even a slight decrease in the quantity of richness of the milk during the period soon adjusts itself and does not affect the child.

BARDENHEUER proclaimed the necessity of extremely radical procedure in tuberculous hip processes, not hesitating to remove large pieces of the pelvis, which possesses immense regenerating power. He fastens the articulation, as he finds that without this measure the musculature of the femur becomes relaxed in time, and the femur finally slips past the acetabulum.

WOLFF reported nineteen cases of extensive resection of the pelvis for tuberculosis with abscesses in 80 per cent., in one case extending from the iliac crest to the knee. The anamnesis is especially important in the diagnosis as even a trifling injury may induce it. Many persons who are suspected of simulation or neurasthenia are in reality affected with tuberculosis of the spondylosis sacro-iliaca, finally disclosed by the breaking through of an abscess. Suppurating meningitis or rectal paralysis may follow the extensive operation, but less effective intervention is sure to leave a permanent fistula. He endorses Bardenheuer's method, which he has followed in twelve cases with five deaths. The first incision is carried along the iliac crest to the spina ant. sup., followed by a perpendicular incision to the sacrum, close to the spondylosis. The lower transverse incision is then made as far as the tuber ischii. The whole of the musculature is then raised with the periosteum, followed by an incision along the labium int. cristae iliei; subperiosteal detaching of the psoas from above downward, and sawing with the Gigli saw for the foramen to the spina ant. inf. The ileum can then be worked loose. He showed some radiographs illustrating the remarkable regeneration of the pelvis afterward.

KRABEL described the twelve cases in which he has extirpated the spleen, with seven recoveries. If there is prolapsus, it is apt to be dangerous.

LEICHTENSTERN called attention to the cystitis and tumors in the bladder which affect persons handling toluidin and naphthylamin in anilin works.

NAUNYN, in his address on "Cholelithiasis," advocated surgical intervention in acute and chronic cystitis, cholangioitis acutissima, but with incarcerated stones, chronic cholangioitis, and pericholangioitis with adhesions, fistula or carcinoma, the intervention should be preceded with a thorough Carlsbad course. He recommends a course at home, drinking, morning and afternoon, three or four glasses of Carlsbad water—the artificial preferred, never the dissolved salts—and lying down for three hours twice a day, with large, thick, linseed cataplasms over the region, avoiding beer and wine, fat and raw food. In seeking carcinoma metastases he warned never to forget to palpate Douglas's pouch. Löbker's statistics showed two deaths out of 172 cases operated in the last eight years (157 women and 15 men), of whom 10 per cent. had carcinoma.

Other communications on "Formaldehyde Disinfection," "Malt Soup for Sick Infants," "Tetanus," etc., have already been summarized in the JOURNAL.

SCHLOSSMANN exhibited his disinfecting apparatus, which filled the hall with mist in a few minutes.

Ninth Italian Congress of Internal Medicine.

GUIDO BACCELLI turned from the duties of Minister of State to preside over the meeting of this congress at Turin in October. He mentioned in his opening address, as an instance of the marvels accomplished by the endovenous injection of heroic medicines, that Robert Koch, who is now in Italy making a comparative study of "Malaria," after his experiences in South Africa, was recently examining a couple of cases of extremely severe pernicious "malaria," one in the pre-agonic stage, and requested that the cadaver be sent to him the next day, but a single endovenous injection of quinin placed the patient on his feet again to the amazement of all. The subjects for the day were

VENESECTION AND ORGAN THERAPY.

He observed that he had seen most remarkable results follow venesection, especially in capillary bronchitis and acute nephritis. He explains its action in the latter case by the fact that the peripheral pressure of the effusion in inflammation of Bowman's capsule, presses on the small blood vessels and retards the circulation through the delicate apparatus of the glomerulus, from which the entire functional economy of the kidney suffers; the epithelium undergoes fatty degeneration, and the urine diminishes in quantity with symptoms of progressively increasing toxemia. He has saved and even secured complete regeneration of the kidney in hundreds of cases like this by opening a vein in the foot. Rummo concluded his address on organ therapy with the remark that this new branch of therapeutics is firmly based on observation and experience, but requires additional research, which should be conducted patiently and seriously, without sensational notoriety. Bozzolo summed up the question from the practical point of view that the thyroid has a most important position in therapeutics; the thymus and ovary are also important, the testes of some utility and the kidney and liver promising. No other organ has as yet found practical application.

MARAGLIANO'S address on "Venesection" confirmed the benefits and limitations of phlebotomy as proclaimed by Galen: "the depletion and depuration of the organism," adding that Sanguirico has established that within certain limits, venesection never produces functional alterations nor disturbances in the nutrition in animals. He also states that the muscular fibers of the heart are nearly always found slightly altered in dogs, enough to suggest fatty degeneration, which some investigators have noted after venesection, to which they attributed it. He has also observed a certain number of tiny drops of fat in the capillaries of the dog's brain in the normal condition, which also throws light on the fatty degeneration of the capillaries observed in anemia consecutive to venesection. The composition of the blood, he continued, is not constant, but subject to changes, which, however, never affect any of the functions of the organism. He even considers it possible that the entire number of corpuscles are not all actively engaged at once, and that a part can substitute and perform the function of the whole. He reported a number of tests and experiments demonstrating that impoverishing the blood has no injurious effect upon the evolution of infective diseases, but is even directly beneficial when the lungs are not working properly and are unable to eliminate the excess of carbonic acid formed in a blood particularly rich in red corpuscles. Traube expressed this fact when he stated that persons whose blood contains less red corpuscles than the average are less affected by pulmonary disturbances than others, and even a small amount of lung surface is sufficient to eliminate their carbonic acid. This fact explains the manifest improvement after venesection in pneumonia, which he has observed again and again in his own practice; the dyspnea and cyanosis decrease, while the elimination of carbonic acid increases. On the other hand, in cases of circumscribed pulmonary lesions, the elimination of carbonic acid decreases after venesection, showing that the elimination had been practically normal. Recent research (Robin) has proved that venesection promotes oxidation processes in pneumonia, and everything tends to the assumption that when the corpuscles are inert they are useless. He agrees with Zakharine that venesection is especially beneficial in active congestions with hemorrhage, especially of the respiratory apparatus and brain. The amount necessary to obtain the mechanical effect required in these cases is from 200 to 400 c.c. Zakharine even ascribes a *revulsive* action to phlebotomy.

claiming that the congestion may be drawn to a remote vascular region, and Calabrese added two corroboratory observations of severe, rebellious hemoptysis in tuberculosis, arrested by a few leeches applied to the base of the thorax. Maragliano also dwelt upon the advantages of venesection in eliminating the toxins circulating in the blood, especially in renal or pulmonary insufficiency, or when there is some obstacle to the passage of bile into the intestines, and also in the auto-intoxications resulting, usually, from the suppression or functional alteration of the organs designed for the defense of the organism against the poisons it manufactures spontaneously. Bouchard has demonstrated that 500 grams of blood taken from an uremic subject contains 8 grams of extractive matters, i. e., about the same amount as is eliminated normally by the kidneys during the twenty-four hours. The attempt has been made in cerebrospinal meningitis to clear the blood by venesection of all the toxic substances accumulating in it, and favorable results have been obtained with it in diplococcic toxemia, combined with salt solution, especially in regard to the complicating hypostyptic phenomena, although these facts are not yet fully established. In uremic intoxication, an amount varying from 500 to 1000 c.c. is withdrawn. The simultaneous injection of salt solution, preventing variation in the blood pressure, enables a larger amount to be taken than would be otherwise possible. Attempts have also been made to stimulate the formation of blood in rebellious anemia by withdrawing a small amount, 50 to 100 c.c.

CHLOROSIS.

RIVA ROCCI explains chlorosis as the result of an insufficiency of the biochemic function of the red corpuscles, combined with a lack of hemoglobin. The "hypoglobulia" and poikilocytosis are merely secondary causes. Aporti's investigations have established that in vertebrates, the cytogenesis and the hemoglobin genesis are independent of each other. The corpuscle is born colorless and gradually takes on color as it manufactures its own hemoglobin out of the iron in the organism. The corpuscles of chlorotic subjects seem to have less aptitude for the manufacture of hemoglobin. If this primary cause of chlorosis is admitted, it is easy to understand the heredity of chlorosis, its recurrences, appearance at puberty, etc. He reported research which proves that iron increases the amount of hemoglobin, while arsenic increases the number of the red corpuscles. He noted the remarkable improvement attained with Bland's pills, taken in the large dose of twenty to twenty-five a day.

DE RENZI emphasized the benefits and complete cures secured with rest in bed, and Devoto reported eight chlorotics in whom absolute repose produced prompt and decided improvement, without iron. The appetite returned in ten days and the cure was complete in forty, in a case he described at some length. Zoia mentioned that Bizzozzero's demonstration of the formation of the red corpuscles in the marrow in adults, led him to study the ferratin in the marrow, and he was surprised to find it only present in the most insignificant amount, compared to what is found in the liver, which fact confirms Riva Rocci's theory.

DE DOMINICIS attributes the albuminuria to gastro-intestinal autointoxication a certain, sudden, intense albuminuria observed, with edema, in which the kidneys are no more involved than the other organs, and return to normal with appropriate dietetic measures or lavage of the blood.

"Post-infective Interstitial Nephritis and Renal Sclerosis" were explained by Patella, who injected animals with urine from pneumonia and typhus patients, finding that the pneumococcus and Eberth's bacillus are capable of producing various alterations in the kidneys, especially interstitial nephritis, from which a sclerous process develops.

BENVENUTI announced that "primary splenomegalia" is the result of an intoxication and not of an infection. It is difficult to differentiate from pure splenic anemia, but is indicated by cirrhotic alterations if they are present, although there does not seem to be any connection between the lesions of the spleen and those of the liver in many cases. The splenic lesions are characterized by fibro-adenia.

MARENCHI described regeneration of the peripheral nerve-fibers, from some experiments in which he had cut the pneumogastric on one side and fifteen days later on the other, and six days afterward excised the portion of the nerve first cut with the cicatrix. The microscope revealed the entire absence of nerve-fibers at the cicatrix, from which he concludes that the re-establishment of the function of the severed nerve does not depend upon its regeneration, but is effected by means of collateral nerve routes.

BUSCHINI called attention to the diagnostic value of the slightrhythmic jerks of the head that accompany the pulsation

in cases of aneurysm of the aorta, noted by Coop. They disappear about twenty-four hours before the rupture of the aneurysm, and may disappear partially or entirely if clots form in the aneurysm.

In connection with the Congress there was a most interesting exhibition to illustrate the history of medicine, with autograph works and reproductions of the priceless treasures of the Vatican and other museums, and collections throughout the country, among them Leonardo da Vinci's anatomic drawings with his autograph notes in his peculiar style of "mirror writing." One case contained reproductions of the votive offerings and designs carved on the pillars of the ancient temple of Esculapius at Tevere. There were also autograph and unpublished manuscript by Malpighi, Rolandi, and other famous names. The *Gazzetta degli Osp.* of October 2 contains reproductions of some of the curious illustrations of these early works on medicine.

Italian Congress of Hygiene.

Turin not only welcomed the Congress of Internal Medicine in October, but also the Congress of Surgery and the Congress of Hygiene, all three remarkable for the number of leading men, who occupy important political positions, in which respect Italy is exceptionally favored.

Among the subjects treated was the success of Professor Sclavo's serotherapy of anthrax, which has been found effectual not only in animals but in man. The Congress passed resolutions urging the government to provide means to produce this serum on a larger scale.

MATTEI reported the efficacy of fluid extract of lemon in the prophylaxis and cure of "malaria," confirmed by the experience of a number present, but for fear that the lay public might be led to neglect the use of quinin, the lemon treatment was not generally endorsed, and the subject was referred to the next congress for further discussion.

OTTOLENGHI stated that a three per thousand solution of corrosive sublimate will not kill the bacilli in tuberculous sputa, but this is accomplished with a 10 per cent. solution of lysol. It was decided that this matter be agitated until an unfailing disinfectant be definitely accepted for this purpose.

The necessity of greater uniformity in the technique of bacteriologic analysis of waters, was emphasized, to enable comparison of the work in different laboratories.

Resolutions were passed in favor of a central department of public health, and the Congress adjourned to meet next year at Como, where the centennial of the invention of the Voltaic pile is to be celebrated.

SELECTIONS.

Gheel Insane Colony.—The *Charities Review* for October considers the question of the influence of a colony of demented or feeble-minded upon the neighboring community. To begin with, it should be borne in mind that the Gheel colony for Belgic insane dates back about thirteen centuries, beginning on a small scale and progressing with varying fortunes until the present, when almost every home in the town is a part of the great cottage hospital utilized by the State. For all these centuries the insane have had the run of the streets of Gheel, and the citizens' familiarity with the whims and caprices of their guests eliminates every look and tone that might point to any inequalities of condition, and in time the newcomer learns to act as he sees others act. When a new patient arrives he is taken to the infirmary, a comfortable building in the outskirts of the town. Here the first diagnosis is made, and if there is no fear of violence to himself or others, he is put in the general ward for closer observation. The nurse is summoned to take to his home his new charge, and he is told as much of the patient's history as he should know, in addition to explicit directions as to the diet and care that is demanded. The patient is taken at once into entirely new surroundings; into a home, in fact, where he will be regarded with interest and not suspicion. Occupation is also provided as far as possible and the guest encouraged by pay and praise to assist in the work of the house or farm, and in the withdrawal of his

thoughts from himself he takes an interest in the joys and sorrows, trials and labors of those around him. The rules do not allow any family to take more than two patients, and prescribe in explicit terms the care which they must receive, the way in which the rooms must be furnished, the clothing to be worn, the beds on which they sleep, and the food provided. The physician must visit each patient at least once a month, and the inspectors drop in at irregular intervals. Since the majority of the households of Gheel are supported by their insane boarders it is important that the rules should be obeyed, but this is not the only motive for acting humanely. When we recall that for generation after generation the people have been daily exercising patience and showing sympathy, it is easy to see that it is the very nature of these people to be kind and gentle. One of the questions which frames itself in the minds of all who hear of this unique institution is: "How does this large contingent of feeble-minded affect the native population?" The daily association with the simple from childhood on would surely influence more and more each generation, but it does not appear to be the case, and in fact, the great success which has attended the college at Gheel proves conclusively that the Gheelois are as clever as any of their neighbors. The explanation for this unexpected immunity from mental atrophy is that the entire population is apparently oblivious to the presence in their midst of anything abnormal. If this were not the case, it is easy to see how 2000 insane living in the homes and walking the streets might cast a blighting influence over their environment. The colony releases as cured or benefited a yearly average of perhaps 20 per 1000, although efforts are made to reserve the colony for the least promising cases, keeping the curables at home.

Health Resort in Southern India.—The mountain resorts at Simla and Darjeeling, India, are comparatively familiar names to English and American readers, but Kodaikanal, a sanitarium nearer the south end of the peninsula, is seldom spoken of. It is 7200 feet above the sea, near the summit of the Pulney mountains, and has been especially advantageous to missionaries for nearly half a century. Two American missionaries were the first to ascend the precipitous mountains and find there a relief for the deadly burning heat of the lower plains. Groves, springs and a lake exist and add to the climatic attractions of the place, and a railroad now runs not far from the foot of the peak. Stone houses have been erected around and above the lake, and their accommodations are well nigh exhausted during April and May, the two most trying of the hot months of the year, in Southern India. It is a great boon for the adult members of the foreign missions, and also for their children, to have this outing, which saves in many cases the expensive trip to America, when recuperation becomes imperative. Rev. Jacob Chamberlain, M. D., writing to the *Missionary Review* about the history of this lofty resort, says: "It is singular that nearly all the great sanatoria of India, north and south, are at practically the same elevation above the sea, Simla being 7116, Darjeeling 7168, Ootacamund, 7271, Kodaikanal 7209. Simla is the summer capital of the Viceroy, Darjeeling of Bengal, and Ootacamund of Madras, and hosts of government officials, with their families, accompany the governors there, and other Europeans swarm those places. Kodaikanal, however, is a smaller and more quiet place. Its climate is less damp than many of the hill stations. Being nearer the equator, in latitude 10 degrees and 15 minutes north, its climate varies but little in different seasons of the year. The thermometer 100 feet above the lake never goes below 40 degrees in the cold months, and it never rises above 76 degrees in hot months. In January and February, frost is seen on the shores of the lake, but never 100 feet above. In April and May, the hottest months, the mercury seldom marks above 75 degrees or below 60 degrees, thus varying less than

15 degrees night and day, week in and week out. Essentially the same of the temperature during the hot months of the year, might be said of nearly all the great sanatoria of India. There is not the real tonic effect of frost upon the system. It does not build one up who is run down as a winter in the temperate zone does; but an occasional change to one of these sanatoria is exceedingly helpful in preventing the utter breakdown that has wrecked many a promising missionary career too near its beginning.

New Mexico as a Health Resort.—In *Public Health* for September, Dr. Curtiss Bailey writes at length and with illustrative diagrams, regarding certain climatic peculiarities of "the dry belt of the West," especially of Las Vegas in New Mexico. The climate of New Mexico, though far from ideal, can only be understood and appreciated by comparison with that of other States and countries. A survey of its climatic conditions, such as its altitude, its southerly latitude, its even average temperature, its low humidity, the small amount of precipitation, its excess of sunshine, the minute amounts of aqueous vapor contained in its atmosphere, its isolation from large populous centers, its great distance from large bodies of water, its immunity from high winds and sandstorms, and its freedom from unsanitary surroundings, should convince the reader that there does not exist a better or more ideal climate for the elimination of disease and the restoration of health. One of the prime factors of climate is wind. While it is true that severe winds scour the high plateaus and mesas of the Rockies, yet in localities like Las Vegas Hot Springs, which is situated beneath and sheltered by foot hills, high winds never occur. At Santa Fé, a town fifty miles distant, where the velocity of the wind is, if anything, in excess of that of Las Vegas Hot Springs, we find the annual velocity 60,891 miles. This compares favorably with certain other American cities. The prevailing winds, which are westerly, cross the snowclad peaks of the Rockies, and those foot-hill districts which, covered with terebinthinate growths, saturate them with balsamic odors and healing powers. No large cities interposing to contaminate them, the air here compares with that of midocean, the purest known. The coolness of the nights, which renders sleep possible and pleasant, is explained by the difference which exists between the sun and shade in high altitudes as compared with sea-level. It is estimated that for every 235 feet rise, a difference of 1 degree F. is found between sun and shade. This accounts for the warmth of the sun early in the day, and also explains the rapid fall of temperature at sunset. There is no doubt that the beneficial effects of sunshine increase with altitude. But favorable as may be these conditions, the vast differences do not exist which are generally accredited New Mexico as compared with lower altitudes. Nature demands the same from her children wherever they be; her laws are equally in force everywhere. The conveniences and luxuries of home life can not be sacrificed by the invalid upon the altar of climate. The intelligence, direction and watchful care are as important in one locality as in another. The bed-ridden at home can not rough it on the plains and mountains of New Mexico and expect favorable results. Many have been the disappointments because of such erroneous impressions. Exposures at home, due to atmospheric changes, are both frequent and dangerous: the same is true in New Mexico, even though it be in a lesser degree. The patient needs medical assistance and attention as much on the table-lands of the Rockies as within his native environment. Whatever is necessary for the recuperation and restoration of health at sea-level is equally essential in New Mexico, for climate, though of primary importance in combating disease in the more serious affections, must call to its aid those methods which, applied under less favorable atmospheric conditions, are of no avail.

PRACTICAL NOTES.

Gastric Fermentations.—The following mixture is prescribed by M. Einhorn for the fermentations connected with gastrectasia from stenosis of the pylorus: Resorcin 4 gm., bismuth subnitrate 20 gm., aq. dest. 200 gm. A tablespoonful in a glass of water half an hour before meals three times a day.—*Semaine Méd.*, September 14.

Intrauterine Injections.—Tipiakoy recommends in salpingo-ovaritis and parametritis, irrigation of the uterus with a tepid five per thousand solution of sublimate, continued for three or four weeks. It is also very beneficial preliminary to an operation on the adnexa, by reducing the tumefaction and inflammation.—*Semaine Méd.*, August 24.

Hemostasis with Gelatin.—All the inconveniences of tampons and the dangers of renewing the hemorrhage when they are renewed, after ablation of tumors of the nose, are avoided by dropping a little 1 per cent. gelatinized water from a syringe on the pedicle of the tumor after the first severest gush has been arrested by compression. The clot forms almost instantaneously. Every time the blood appears, check it afresh with the gelatin, warning the patient not to blow his nose, and to stay in bed twenty-four hours, and instil gelatinized or oxygenated water every two hours.—*Semaine Méd.*, September 14.

Treatment of Varicocele.—The assistant stands at the right of the reclining patient and pushes the testes up against the pubis, holding the scrotum between the fore and second finger of his left hand, while with the right he draws out the double wall of the inferior portion into a flat, square apron. The operator then inserts a Reverdin needle into the scrotum just below the testes, and a ligature is made, passing through the derma and tied moderately tight, so that the drawn up bag thus formed of the under portion of the scrotum, hangs directly beneath the testes, neither in front nor behind. Chloroform is unnecessary.—Professor Nimier: *Revue de Chirurgie*, October 10.

Mitigations of Graves' Disease.—Dr. Roland G. Curtiss of Philadelphia (*Internat. Clinics*, Vol. iv, Series v, p. 78) concludes an article on this affection as follows: Graves' disease is hereditary, therefore the marriage of those having such an inheritance should be discouraged. A person with such an inheritance should reside at an elevation of more than 500 feet; should avoid great excitement or any highly exciting occupation; should shun a residence in a limestone region, and hesitate to select a home in a locality where the disease is common, no matter what the locality may be; and should avoid any cause of anemia, as well as excessive study, prolonged mental or sexual strain or anything likely to induce a neurasthenic condition.

Ergot in Chronic Malaria.—Jacobi (*Med. News*, October 22) reports cases and concludes from his use of ergot that: 1. Certain cases of chronic intermittent fever occur, with large tumefaction of the spleen, which, having resisted the action of quinin, arsenic, etc., are benefited by ergot. 2. The contracting effect of the ergot is noticed within a reasonable time, when the splenic enlargement is not old or firmly established. 3. The attacks will disappear before the diminution in the size of the spleen is very marked. 4. Chills are not noted, as a rule, after the use of ergot, though temperature remains irregular. 5. Plasmodia do not disappear so rapidly as with quinin, where the latter is effective, though many apparently intractable cases get well with ergot.

Aneson, the New Anesthetic.—This is a colorless, aqueous solution of trichlor-pseudobutyl-alcohol or acetone-chloroform and corresponds to a 2 to 2.5 solution of cocain, but has none of the latter's local irritation and is non-toxic. As much as seven-

teen grams have been used without after-effects. The anesthetic effect is also immediate, with no interval, as with cocain. In suturing, a small amount of aneson injected at the points where the stitches are to be taken will prevent pain. Even inflammatory phlegmonous processes can be rendered perfectly insensible if sufficient aneson is used to keep them flooded all the time. The anesthesia was not perfect in all cases, but this can be said of all other anesthetics. L. Sternberge of Berlin concludes his report of a dozen tests of aneson in the *Klin.-Therap. Woch.*, of September 25 by recommending it as a useful and safe anesthetic.

Peripheral Neuritis.—The connection between peripheral neuritis and chronic deforming rheumatism is evidenced by thirteen observations on record in which a peripheral neuritis was noted with chronic deforming rheumatism, one observation of spinal meningitis and six observations of alterations in the spinal cord accompanying pronounced peripheral neuritis. Pitres and Carrière comment on these cases (two personal) that the neuritis is not the essential cause of the rheumatism by any means, but probably plays an important part in the production and localization of the trophic alterations of chronic rheumatism and is itself the effect of the antecedent lesions of the tissues or of the humors of whose nature we are still ignorant. The neuritis is evidently a sort of intermediary between the general disease, the rheumatism, and the articular dystrophy.—*Archiv Clin. de Bordeaux*, August.

Purulent Ophthalmia and Ophthalmia Neonatorum.—In these diseases Jenkins (*Med. Record*, October 29) uses the following: Argenti nitratis, gr. v-x; acaciae, 5i (or q. s.); aqua destillatae, 3ss; petrolati liquidi, 3ss; to be made into an emulsion and shaken well before using. He believes the various potent solutions and crayon applications often do more injury to the eye than the diseases, and that this emulsion is the least injurious and most efficacious in all forms of purulent disease of the eye. In the initial stage the customary treatment for blennorrhea is to be followed, the emulsion resorted to on the establishment of suppuration, when, the patient on his back and the lids everted, the eye being cleansed with a hot 1 to 5000 sublimate or potassium permanganate solution, two or more minims are dropped into the eye. The surgeon should then manipulate the everted lids so that the emulsion penetrates "to the utmost recesses of the folds of transition of the conjunctiva." The emulsion should at first be used every twelve or twenty-four hours; afterward twenty-four, forty-eight or sixty hours, until the discharge entirely ceases.

Gelatin in Aneurysms.—Lancereux presented a couple of patients at a recent meeting of the Paris Académie de Médecine, cured by subcutaneous injections of 150 to 250 c.c. of a solution containing 2 gm. of gelatin to 100 gm. physiologic salt solution. One patient had received twelve injections in the gluteal region between January and May, and two new aneurysms, appearing lower down, were definitely arrested with a single injection. Nature heals an aneurysm by the formation of clots in the cavity of the sac, until the lumen becomes as small as the rest of the artery. The aim of therapeutics should therefore be to assist nature in the formation of these clots, and this can be accomplished by rendering the blood more coagulable with gelatin. A sac-shaped aneurysm, with its slower current and uneven walls, is especially amenable to this treatment, but a spindle-shaped dilation is not affected by it. He reported five observations and Huchard another. The latter by this method has arrested uncontrollable hemoptysis in a tuberculous patient. Fournier called attention to the extreme frequency of syphilis in the etiology of aneurysm of the aorta, noting that one of the patients presented was a syphilitic, and mentioned a new cause of error in the diagnosis of aneurysm of the aorta of syphilitic origin: the appearance of a large gummatous patch in front of the aorta, which presents every indication and is accompanied by all the symptoms of aneurysm of the aorta, but is in reality nothing of the kind. It yields readily to specific treatment, but it must not be supposed that it is an aneurysm that has been cured.—*Bulletin*, October 11.

MEMBERSHIP IN THE AMERICAN MEDICAL ASSOCIATION.

This is obtainable, at any time, by a member of any State or local Medical Society which is entitled to send delegates to the Association. All that is necessary is for the applicant to write to the Treasurer of the Association, Dr. Henry P. Newman, 100 Washington St., Chicago, Ill., sending him a certificate or statement that the applicant is in good standing in his own Society, signed by the President and Secretary of said Society. Attendance as a delegate at an annual meeting of the Association is not necessary to obtain membership.

On receipt of the subscription the weekly JOURNAL of the Association will be forwarded regularly.

Gentlemen already members of the Association should send their annual subscription to the Treasurer, or direct to the JOURNAL office.

All communications and manuscript of whatever character, intended for publication in the JOURNAL, should be addressed to the Editor, and all communications relative to the business of the JOURNAL, proof-sheets returned, or in regard to subscriptions, should be addressed to THE JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION, 61 Market Street (Occidental Buildings), Chicago.

Original communications are only received with the understanding that they are exclusively contributed to this JOURNAL.

SATURDAY, NOVEMBER 12, 1898.

THE RELATION OF MALARIA TO RENAL DISEASE.

The profession is coming to recognize more and more the interdependence in health and disease which exists between the various organs of the body, and that maladies which exert their primary and dominant influence upon one organ may simultaneously or consequently seriously derange another part far removed from the site of the early lesion. In no organs of the body is this interdependence of function better developed than in those which occupy the abdominal cavity, or lie in adjacent parts, and as a result of this we see secondary renal changes following diseases in the liver, the spleen and the intestinal canal in a considerable number of maladies. It is, however, particularly in those diseases which are called infectious that the kidneys are apt to suffer, for they are the organs by which the toxins or poisonous matters produced by the infecting micro-organism must be chiefly eliminated from the body, and it is for this reason, in all probability, that nephritis so frequently follows scarlet fever and other acute infections. As the years go by it becomes evident that primary renal disease is much less frequent than it was originally considered to be and more commonly it is recognized as a purely secondary affection.

In this connection recent studies which have been made concerning the influence of malarial infection upon the kidney are of very great interest, and it seems to be the universal experience of those who have made a careful study of malarial infection that albuminuria indicating renal difficulty due to malaria is exceedingly common. Thus OSLER states that it

occurred in 46.4 per cent. of the cases in his wards, and THAYER has recently shown that casts of the urinary tubules were found in 17.5 per cent. of the cases, indicating that there was a true inflammation of the kidney in these cases of the disease. Furthermore, he has also shown that in 1832 cases of nephritis, 26 were of malarial origin. In confirmation of these statistics KERLEY has also reported the case of a child of 18 months who developed malarial nephritis, and he quotes MONCORVO's article, in which it is stated that in Rio Janeiro it is not rare to find children suffering from acute nephritis as the result of malarial poisoning.

FRUITNIGHT has also reported similar cases, and it is evident that physicians called upon to treat malarial cases should carefully watch the state of the kidneys by a constant examination of the urine.

These facts are also interesting in connection with the well-known antagonism of many prominent practitioners to the use of quinin in malarial fever, associated with renal changes, and we believe that great caution is necessary concerning the use of this medicament, particularly when the kidneys are involved, first, because quinin in large doses acts as an irritant to the kidney, and second, because it has been found in cases where the kidneys were manifestly impaired that the drug seemed to produce serious renal complications. No less an authority than Koch, on his return from Africa, has asserted that the abuse of quinin in severe malarial infection of the estivo-autumnal type is responsible for many of the complications seen in the malignant forms of malarial fever in that country. It seems to be universally agreed that it is the estivo-autumnal parasite which most frequently produces nephritis. Yet this is the type in which the physician is most tempted to push the drug, as it is the least affected by ordinary doses of quinin. In other words, that form of malarial infection which, by its persistency, would lead to the use of large quantities of quinin also produces a condition of the kidney which makes the use of large doses of this drug of doubtful advantage.

A PSYCHOLOGIC QUESTION OF PRACTICAL IMPORTANCE.

Once in a while, but fortunately not very often, we hear of an accident by land or sea which is utterly unaccounted for on any ordinary rules guiding human conduct, and which seems to demand, or at least justify, the presumption that there are psychologic moments, in which, without any special stress or emergency, there is sometimes a sort of mental vertigo concerning more particularly the judgment of those in whose hands important interests are placed involving property and even human life. A few years ago a great English battleship went down by collision, the latter directly due to orders given by the admiral, who at the time was considered the most promising and

competent of his rank in the British navy. An order was given by him, and repeated in spite of all the remonstrances that the strict discipline of the service would permit, that ignored the plainest rules of common sense, and the carrying of it out cost the lives of some four hundred British sailors and of one of the most formidable of England's fighting ships. It appeared from the inquiry into the disaster that there was no revealable cause for its occurrence other than some inexplicable mental condition on the part of the admiral, by reason of which he had, in spite of his perfect knowledge of the facts, considered the safe turning radius of the ship to be some hundreds of feet less than it really was, a sort of mental process in which one ordinarily a good mathematician will for the moment conceive that two and two make five or some other equally improbable proposition. Other similar instances can be adduced; a conductor, for example, in spite of explicit train orders, signals his engineer to start out to certain disaster, and very recently a powerful, well-found steamer was lost with serious sacrifice of human life under conditions that are difficult to appreciate without some such presumption as has been mentioned. The ship was miles off her proper course, was headed in the wrong direction; the captain, one of the most trusted and reliable of all those employed by the company owning the ship, was himself in charge of the deck at the time of the accident, and the rocks upon which the vessel struck were well-known dangers, while the conditions of weather, daylight, etc., were not such as to excuse the disaster on other grounds.

It would be natural to suppose that the temporary mental derangement that caused these accidents might be due to alcoholic indulgence on the part of those responsible, but this probability seems to be ruled out by the evidence in some cases, and we must look further for the cause. It can not, moreover, be commonly attributed to mental strain or excitement, for such conditions often are notably absent. We seem to be restricted by exclusion to this view: that able and competent men are subject, under certain special conditions which are, as yet, not clearly understood, to a paralysis of judgment, or rather, perhaps it should be said, to an absolute inability to realize at the moment the real relation of things and the consequences of this non-recognition. This theory has been strongly brought out in the discussion of Admiral TRYON's case, and it has much to be said in its favor. In minor matters we not infrequently hear people say that they can not explain why they did this or that irrational act; the impulse of the moment, a partial defect of attention or some other excuse generally serving for an explanation at the time. It is only when the consequences are serious, as in case of shipwreck or railroad disaster, that the subject receives much attention or excites general interest. That such conditions should occur in those who have

the most important interests in charge makes the subject one of special importance, requiring careful inquiry into the causes and prevention, especially in those whose judgment and attention are taxed. The question arises whether they may not be overtaxed and this be a direct cause of their occasional failure. It is well known that locomotive engineers sometimes break down completely after long-continued nervous strain, and are then sometimes even subject to hallucinations that affect their judgment in critical cases. This, however, may be another matter altogether from the momentary intellectual derangement that makes a shipmaster or railway conductor give an order directly contrary to his own better judgment, with disaster, it may be, as the result. We may assume that there is in some of these cases an intellectual *petit mal*, but it is more reasonable to refer them to something less distinctly pathologic and more in the common order of events. Such errors of attention and judgment must be occurring frequently in common life, but being without specially evil consequences, they are commonly overlooked or forgotten. That they may occur also when every reason should be against it, and in those who by education and training ought to be particularly on their guard against them, only raises the question of their investigation.

A study of all known accidents from this cause, taking into consideration not only the habits, conditions, surroundings, age and all other circumstances of those responsible, would be a possibly valuable contribution, but thorough and extensive investigations into the pathology of attention generally are likely to be the means by which we are to obtain the more practically valuable results. The time may come when those in responsible positions requiring quickness of attention and perception and reliability of judgment, like certain railway employes and other officials, will have to undergo examinations by trained psychologists, to test their fitness in these respects. At present we require tests for the special senses and some of their refinements, such as color perception, but it is not hard to see that the faculties of attention and intellectual quickness are even more important. It is hard to find accidents by land or sea that can be exclusively attributed to color blindness or other special defects, but some temporary higher intellectual aberration is fairly forced on our attention as a cause of such disasters.

BLOOD CRYSTALS.

The hematologist frequently encounters under the microscope crystalloid bodies of varied shapes and sizes. As a rule these are without any practical significance. Their presence, however, may be accounted for in various ways. In the first place they may be of hemoglobin. We have known for a considerable time that though the hemoglobin of human blood

resists laboratory crystallization, that of some of the lower animals, notably the guinea-pig, can be readily crystallized outside the body. In the healthy blood crystallized hemoglobin can be easily demonstrated: a large drop of blood is placed upon a slide, and after coagulation of the margin has taken place the cover is lowered gently, and after from twelve to twenty-four hours the hemoglobin appears as rhombic crystals. In diseased blood, and particularly in leukemia, pernicious anemia, and the septic processes, septicemia and pyemia, it appears much earlier—from a few minutes to a few hours. It may be noted here that human hemoglobin always crystallizes as reduced hemoglobin, a point which may serve to distinguish human blood from that of the lower animals. It would seem that from the readiness with which crystallized hemoglobin appears in conditions of the blood attended with destruction of the red corpuscles, its early presence indicated a retrograde condition on the part of the blood.

Hematoidin crystals are of more frequent occurrence. They are almost always described as a constituent of old blood extravasations, cysts, spleen infarcts, old thrombi, and especially old cerebral softening. In the anemias, pernicious anemia and leukemia, these crystals are often found within the white corpuscles, though this may occur in a specimen of healthy blood as well.

Found more frequently in leukemic blood than in any other diseased condition are the so-called CHARCOT-LEYDEN crystals, though they are by no means peculiar to this disease. They occur as long, colorless, pointed needles, and are identical with the spermin crystals found in the seminal fluid. It would seem from the above that, as far as our knowledge now extends, the presence of these crystals aids us practically nothing in the study of the blood, the only fact of importance being their early presence and in increased numbers in blood which is undergoing a progressive loss in its vitality.

THE ASSOCIATION OF TRAUMATISM AND INFECTION.

During the early part of 1898 we published in the JOURNAL an editorial dealing with this subject, in which it was pointed out that the relationship between traumatism and infection possessed an interest not only to the medical man, but also to the lawyer, in that comparatively mild injuries might result in severe infections in so short a space of time that the patient's death might be directly attributed to the accident. As some of the literature covering this matter was quoted in that editorial it is not necessary at present to quote it a second time, but it is interesting to note that very recently two American investigators, CHEESMAN and MELZER, have published in the *Journal of Experimental Medicine*, a research to determine how far injury of a part rendered it susceptible to infec-

tious processes. We need not quote the technique which they employed nor the literature which they studied in the preparation of their research, but it is worthy of note that they found that any interference with the function of an organ caused micro-organisms introduced into the blood to grow with great rapidity and to produce grave injury, and, further, that if one of the organs, such as the spleen for example, were injured and the animal infected with a pathogenic micro-organism, these micro-organisms found lodgment at the site of these lesions and developed with extraordinary rapidity and virulence. They also found that although micro-organisms might be injected into the blood-stream these micro-organisms speedily disappeared from the current and were found congregated, not in the healthy organs, but in that which had been injured. They also cite a remarkable fact, namely, that even after the injection of bacteria into the blood this fluid remains sterile in many instances. On the ground that blood is a liquid tissue it is suggested that it, like other tissues, permits the growth of bacteria only when it has been injured, all of which goes to emphasize the scientific basis for the well-known clinical fact that any condition of injury or debility in one part of the body renders an individual so affected susceptible to almost any infection to which he may be exposed. Thus we see how clinical observation and empiric statements can be and are substantiated by scientific research from year to year. All these facts also emphasize the importance of preparing a patient who is about to be subject to a surgical operation, in such a way that every organ in the body is in proper functional activity and strength, so that it may not be prone to infection should the blood become thrown open to disease micro-organisms. How often do we see tubercular areas attacked by the operator in the bones or in the pelvis, without the physician first taking heed that the pulmonary organs are in as good condition as it is possible to put them in, and how frequently the physician meets with cases in which, as a result of operations, secondary infections have ensued. Many of the cases of so-called ether pneumonia, post-operative nephritis, and similar conditions, might perhaps be avoided if particular pains were taken in every case to have every organ in the body prepared to resist disease to the greatest extent before the patient is put to the test of endurance.

THE COMMISSION EVIL.

An evil has lately sprung up which is not specially creditable to those concerned; this is the practice of paying commissions or rebates by specialists to persons bringing them cases. A few years since the medical world was set sneering, by the well-authenticated report that in a certain city the physicians sent out drummers to board incoming trains and by skilful touting to secure business for their respective employ-

ers. Fabulous tales were told of the wealth piled up in this way, and when the light was turned on this practice, the Legislature enacted a law that all persons engaged in this business should wear a badge. This put an end to this scandal. There is little difference between these now obsolete methods and those now practiced in many of our Northern cities, only that professional men are employed as drummers and the slice of the fee is larger.

Another variety of this commercialism has reached the hitherto honest practitioner in the country. The plan is this: Dr. A. brings a patient to Specialist B. or General Surgeon C. A. says, "here is a man abundantly able to pay a good fee, charge him liberally, but I want one-third or one-half." Should the specialist or the general surgeon refuse to accede to this proposition, the patient is taken elsewhere to some less scrupulous brother.

The wrong is to the unsuspecting victim; he trusts his family physician to send him to the specialist of his selection to be sure, but he has a moral right to expect that selection to be made on honest judgment and not with regard to the division of a great fee. Nor is this practice fair to the specialist and surgeon, for they get the credit of charging an exorbitant fee, only a part of which they actually receive.

No. Let each practitioner have his regular and proper fee, and if any division must be made, let the patient know exactly whom he is paying.

THE WAR INVESTIGATING COMMITTEE.

The War Committee of Investigation visited Chicago this week and took testimony of various volunteer medical officers. Colonel SENN, Dr. CUTHBERTSON and others testified. As the testimony was of general interest we will reproduce it in our next issue.

CORRESPONDENCE.

Braces in Spinal Curvature. A Discussion of a Few Points found in an Editorial of Sept. 10, 1898, in the Journal of the American Medical Association.

NEW YORK, Oct. 31, 1898.

To the Editor:—I observe in the JOURNAL of September 10 an editorial on "Curvature of the Spine," which is so far at variance with clinical observations, scientific facts, and known truths, that I believe, in the interest of the profession and the unfortunate individuals afflicted with this deformity, that a short discussion of the editorial and its subject-matter, will not be wholly out of place.

I quote from the editorial: "What greater mistake can there be in medicine than that of fitting a brace to a child suffering from spinal curvature?" . . . "What folly, what total lack of reason it would seem to put a splint on a weak muscle!" . . . "The fault is entirely one of nutrition and development."

These statements are misleading, both to the profession and to the patient. They are arbitrary in their inception, empiric and unscientific as an edict. These statements would lead the reader to believe that all cases were attended with weak or paralyzed muscles as an etiologic factor. Now, I am prepared

to state and demonstrate that not all cases of lateral curvature of the spine are attended with weak or paralyzed muscles as an etiologic factor. Cases of lateral curvature of the spine, due to a short leg or bad position in sitting, have their origin primarily in bone changes. Many cases of lateral curvature of the spine begin in bone disease located on one side of the body of the vertebrae, which disease leads to a lateral curve by the destruction of bone, and in other instances by the absorption of the intervertebral cartilages and bone from pressure. In such cases the muscles have nothing whatever to do with pathologic changes which take place in the bone. Such cases are not by any means rare nor in the minority, and I would like to ask whether these wholesale edicts which are promulgated in the editorial are intended to apply to such cases as I have just mentioned, which clinical observations demonstrate, and the entire orthopedic profession, perhaps, with an occasional exception, will verify. In such cases, the weakness of muscle occurring on one side (the convex) of the curve is a secondary result, depending entirely on the primary curve in the bone, and surely, to prevent further destruction by absorption of the vertebrae or intervertebral cartilages, a support to relieve pressure is of paramount importance. In deformities of the extremities caused by paralysis of muscle, and more especially so-called spastic paralysis, the only way to prevent bone and ligamentous changes, which would result in hopeless deformities, is by applying appropriate braces and even resorting to extensive tenotomy or myotomy to weaken the strong muscles; thus establishing normal compensation between the muscles. The same rule holds good in lateral curvature of the spine. The spinal column is a flexible lever operated upon by masses of muscle on either side of it. If one set of muscles is two or three times stronger than the antagonizing ones, lateral curvature will result, in spite of gymnastics, massage or electricity, unless the spinal column can be reinforced by a proper brace to hold it in a straight position, to prevent absorption of bone by pressure. I, therefore, can see no "folly nor lack of reason," in applying a suitable support to lateral curvature of the spine, any more than I can see "folly or lack of reason" in applying a brace to a foot paralyzed, to prevent talipes varo equinus.

It may be argued that massage will prevent a clubfoot occurring in spastic paralysis. This I know, with an occasional exception, is impossible, because I have tried it in a large number of cases. It may also be argued that massage and gymnastics, without bracing, will cure all cases of lateral curvature of the spine. This I also know to be an error, because I have seen scores of cases treated with gymnastics and massage by our best orthopedic surgeons in this city, and still these cases have gone on increasing in curve, due to pressure absorption. Proper bracing, together with gymnastics and forcible redressment, should be the rule of treatment in cases requiring it. One may as well attempt to straighten a crooked mast of a ship, which had become warped and bent by the weather, by tightening the shrouds and stays, as to straighten cases of lateral curvature of the spine of the second degree with gymnastics and massage without proper bracing.

Another quotation from the editorial: "There are in medicine and surgery a number of conditions which are hidden from observation and palpation, perhaps they are further obscured by a feeling of uncertainty in the anatomy of the part, and at no time in the course of the disease can we see, feel or measure in millimeters the exact extent of the lesion. The physician will invariably draw down the curtain of obscurity before such a case, lose his clearness of vision and make haphazard thrusts at both diagnosis and treatment." There are many factors in the etiology of lateral curvature of the spine, which the profession know but little about. We are perfectly familiar with pathologic conditions which take place in lateral curvature of the spine. The dissecting room has told the story. We also

know of something like eight or ten different causes of this curvature, but we do not know the whole of them. It is for this reason that I believe your editorial makes a mistake in its dictum in stating: "What greater mistake can there be in medicine than that of fitting a brace to a child suffering from spinal curvature?" This edict would imply a *perfect knowledge of the etiology of all forms of lateral curvature and that it was always to be found in the muscles alone.* This together with, "The fault is entirely one of nutrition and development," is a mistake.

In many cases changes due to nutrition and development are secondary, the curve not being caused by weak or paralyzed muscles, but by other potent agency. e.g., rachitis, bad position, a short leg and even a diseased vertebra. Surely these conditions require bracing, together with proper treatment, after bone changes in the vertebral columns have taken place. Then a little further on, I find all the causes of lateral curvature summed up in the following sentence: "The predisposing causes are prolonged ill-health, rapid growth and rickets, occurring in girls between 12 and 20 years, while the exciting causes may be a one sided position at school, a faulty position in standing, an obliquity in the pelvis, and it would seem from the fact that it is usually right-sided, that a hypertrophy of the muscles on this side acts as a prominent factor." Now, as a matter of fact, the hypertrophy of the muscles is not upon the side of convexity. If the hypertrophied muscles were upon that side they alone would strengthen the spine, and there would be no occasion for gymnastics or other exercises. The paralyzed or weak muscles are always upon the side of convexity and not on the side of concavity.

When the deviation from the median line amounts to more than one-half of the diameter of the vertebrae, it will invariably increase, under any form of treatment short of proper bracing to relieve the pressure at the point of curve, for the reason that the weight of the head and shoulders, upon the flexible spine, while the patient is in an upright position, will constantly exert pressure on that point, and absorption will go on as many hours a day as the patient is in an upright position, no matter if the muscles are developed in strength and size to those of a gymnast.

The illustration appended represents an advanced form of double lateral rotary spinal curvature with its attending bone changes. On the left side the ribs are approximated and even overlapping. The intercostal muscles and ligaments on the left side are put upon the stretch while upon the right they are contracted and have become shortened or destroyed. In the lower curve the transverse processes upon the concave side of the curve have become firmly locked together, as also they have in the upper curve, while upon the convex side of both curves, the transverse processes are as widely separated as the ligaments will permit. In both these curves the vertebrae have become thin and wedged-shaped, the point of the wedge being directed toward the concave curve. The muscles in this specimen were found to be degenerated and almost entirely destroyed over the convexity of the curve, while they were shortened and nearly normal in the concavity of the curves.

The spine is rotated in the direction of each of the curves, following the law that "rotation takes place in the direction of curve." Gymnastics could only be harmful in a case of this kind; nothing but appropriate bracing could arrest the progress of the deformity, and *nothing could be done to change the pathologic curves in the bone.* It would be necessary to change the shape of the thorax and ribs, and lengthen the intercostal muscles and ligaments to effect a cure, which is impossible.

Muscles do not hold the spine erect. There never was a greater error taught. Muscles only balance the spine. Ligaments and the bony construction of the spinal column, together with intermittent action of the muscles to balance the spine, hold the spine erect. Muscles would tire out if they were put upon the stretch for any length of time, as can be illustrated by an effort to hold the arm in a horizontal position from the body; it will quickly fall to the side, and the muscles become temporarily paralyzed. Then, again, poliomyelitis paralyzes groups of muscles, which is a very frequent cause of lateral curvature. How are we going to restore tone to these muscles short of curing the lesion in the spinal cord, inasmuch as we know that these lesions are usually permanent, paralysis of muscles on one side allows of lateral deviation, and the weight of the head and shoulders producing pressure at the point of curve must necessarily result in absorption of the vertebrae by pressure through the lifetime of the individual? On the concave side of the curve will be found the shortened ligaments and shortened fibrous elements of the muscle. We know that when similar conditions exist in the muscles in the lower extremities, and spastic changes have taken place, nothing but a tenotomy and possibly an extensive myotomy will relieve the deformity. *Gymnastics and massage are of little use, or positively harmful in such cases.* The knife and proper bracing, together with gymnastics to assist in strengthening the opposing muscles, if they were not totally paralyzed on the convex side of the curve, are truly indicated.

That "the ligaments are lax and insecure," is not the fact; the ligaments are positively put upon the stretch on the convex side of the curve and upon the concave side are contracted and shortened, together with the fibrous structure of the muscles. Pathologic specimens in my possession, which I have dissected out, demonstrate these facts. The idea that ligaments are "lax and insecure" originated in the *mind* of the "gymnastic" orthopedic years ago. The dissecting-room explains the error, as it has many of the absurd theories in regard to deformities. To the quotation "Apparatus only defeats the object of the treatment in a great majority of cases by preventing development; an apparatus, no matter how skilfully constructed, can not correct a deformity of this kind," I may add that *no amount of gymnastics or other exercises can, or every has, diminished the curve due to bone changes in lateral curvature of the spine.* When the vertebrae have become deformed from destruction of bone, from absorption due to pressure, and changes have taken place in the ribs and intercostal muscles, that deformity will remain; and the sooner writers upon the subject admit this fact the better it will be for both surgeons and patients. The most that can be accomplished is to arrest the deformity by preventing further changes at the point of curve, by pressure, and aid in the formation of compensatory curves. *That apparatus prevents development is as erroneous as the statement is incorrect.* An apparatus which is only worn when the patient is in an upright position, in connection with proper gymnastics and other exercises, does not prevent development, but, on the contrary, such patients will more rapidly develop muscles that are weak than without it. Clinical observations demonstrate this fact. To illustrate: In club-foot the extensor muscles have become weak on account of the feet having been drawn around to an abnormal position, by the stronger muscles putting the weaker ones upon the stretch.

This stretching of the anterior tibial group of muscles produces degeneration and temporary paralysis by pressure. The sheath and fibrous tissue of the muscle are approximated by stretching, making pressure upon the muscle cell. These same pathologic changes take place in the muscle of the back on the side of the convexity, and, as in club-feet, these muscles will not regain their tone until the tension is taken off them, and this is best done, in club feet, by overcoming the deformity immediately, by operating and bracing, and in the spine, by taking the tension off the muscles by putting the spine in an extended position. When the spine is so extended a proper support will hold it so while the patient is erect. This can only be done by an apparatus of some sort or recumbency in bed.

I am very sorry that it was necessary for me to write this letter, but as I stated in the beginning, it seems to me that the points which the editorial mentioned should be open to discussion in the JOURNAL.

A. M. PHELPS, M.D.

"The Jugglery of Statistics"—A Bungling Prestidigitator.

PHILADELPHIA, Oct. 30, 1898.

To the Editor:—In answer to your correspondent who writes under a part of the above title, permit me to quote a reply which appears in the *Philadelphia Medical Journal* of November 5:

"The Jugglery of Statistics, a Reply to an Absurd Editorial" is the title of an article occupying one and one-fourth columns in the JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION of Oct. 29, 1898, and written by Dr. Charles Smart, Deputy Surgeon-General of the U. S. Army. The writer is very scornful and contemptuous of the statistics of medical men in general, and of the *Philadelphia Medical Journal* in particular, viewing all of us from the lofty point of an expert dealing with ignoramuses. He admits the accuracy of the figures given in our editorial, namely, that in the Civil War 66.6 per cent. of deaths were from disease, and in the Spanish War 88.1 per cent. It was this difference that we thought needed explanation, and with all deference to our cynic critic we still think it demands it. This is the way we are disposed of:

"The absurdity of this may be well illustrated by adding to the statistics and ratios given above those derived from the reports of the engagement of Admiral Dewey's fleet on May 1, 1898, at Manila. Dewey's fight lasted only one day. The figures given for the Spanish War covered a period of five months, and those of the Civil War a period of five years and two months; but as the element of time does not enter into the calculations of the ratios criticised this element need not be considered in the engagement at Manila. Here we find that no man was killed, no man died of wounds received, but that one man, an engineer officer, succumbed to heat exhaustion or insolation. Stating these figures as percentages of the total mortality we find: killed 0 per cent., died of wounds 0 per cent., died of disease 100 per cent., as compared with 88.1 per cent. in the Spanish War, and with 66.6 per cent. in the War of the Rebellion. If it is not needful for the Honorable Sirs to give such high consideration to the greater death-rate from disease as compared with the deaths from wounds and deaths on the battlefield in the Spanish War considered as a whole, how serious is the consideration they ought to give to this frightful rate of mortality from disease as compared with that from battle casualties in the Bay of Manila."

Now, is there a schoolboy of ten years of age who could not see the "absurdity of this?" If so, he should be whipped and put to his "arithmetic" again. What right has Dr. Smart to say that "the element of time does not enter into the calculation?" It is precisely this element of time that gives the subject any intelligibility whatsoever. The figures are for the entire periods of the two wars. Were there not a great many days during the Civil War when, no battles occurring, there were no deaths whatever from battle or from wounds, but in which large numbers died from disease? Will not our critic kindly spare us from the necessity of replying to such utter nonsense in future? And will he not also spare us the dis-

courtesy of applying his contemptuous remarks to himself? The death from the heat exhaustion at Manila, by the way, did not occur during, but some time after the battle. The "element of time" being excluded, the percentages of deaths during the entire Spanish-American War were as follows: killed, 0 per cent.; died of wounds, 0 per cent.; died of disease, 0 per cent. Q. E. D.

We add as a postscript to the above two thoughts which, as it occurs to us, have not been heretofore brought out: 1. The Civil War was longer, and therefore the number of deaths from disease would necessarily be enormously greater relatively than in a war of short duration. 2. The figures quoted of the deaths from disease in our recent war were made up some time ago, but since then additional deaths have been occurring every day. And the end is not yet reached. The percentage given of deaths from disease in the late war is consequently too low. Such considerations will have no weight with expert statisticians who think that "the element of time does not enter into the calculations."

Respectfully yours,

GEO. M. GOULD, M.D.

Retarded Delivery.

RYAN, IOWA, Oct. 29, 1898.

To the Editor:—The writer was called Thursday evening, October 20, to attend Mrs. C., a primipara, aged 21 years, with small but roomy pelvis and fine muscular development. Vigorous pains were established by 11 P.M., with the position right occipito anterior. Dilatation of the cervix was soon complete, and matters advanced steadily till early morning when, with the head well down on the perineum, and strong pains, all progress ceased. At 7:30 A.M., the mother showing signs of nervous and physical exhaustion, forceps were applied and the head easily delivered. The cord was found tightly wound around the child's neck. Traction on the cord resulted in severing its placental attachment and the child was quickly delivered. On measurement, the cord was found to be nine inches in length, and had evidently furnished one, if not the chief cause for the retarded delivery.

A. H. SCOTFIELD, A.M., M.D.

BOOK NOTICES.

A Manual of Otology. By GORHAM BACON, A.B., M.D., Professor of Otology, Cornell University Medical College, New York; Aural Surgeon, New York Eye and Ear Infirmary. With an introductory chapter by Clarence Blake, M.D., Professor of Otology in Harvard University. New York and Philadelphia: Lea Brothers & Co., 1898.

This manual, written for students, furnishes in a very compact form all the information they need about the anatomy, physiology and the diseases of the ear. To impress upon the student the close relation of the upper air passages to aural diseases, the author has added a chapter on adenoid growths, enlarged tonsils and diseases of the nasal passages. The book is well written, small and inexpensive and undoubtedly will become popular with the students. It is profusely illustrated, and contains a colored plate representing a brain abscess. If colored plates at all, we should think in a manual of otology a series of colored pictures representing the drumhead in health and disease would certainly be far more appropriate than the picture of a brain abscess.

Medical Communications of the Massachusetts Medical Society. Volume xxvii, No. 3. Boston: 1898.

The contents of this volume are: 1. "Annual Discourses," by William T. Councilman, M.D. 2. "Some Modern Methods of the Treatment of Phthisis and its Symptoms," by Edward O. Otis, M.D. 3. "Types of Habit Neuro-Psychoses," by Edward W. Taylor, M.D. 4. "The Toxin of Diphtheria and its Antitoxin," by Theobald Smith, M.D. 5. "Recent Progress in the

Bacteriology of Typhoid Fever." by Mark W. Richardson, M.D. 6. "Epidemic Cerebro-Spinal Meningitis," by Arthur H. Wetworth, M.D. 7. "The Educational Treatment of Neurasthenia and Certain Hysterical States," by Morton Prince, M.D. 8. "The Question of the Curability of Cancer of the Breast," by J. Collins Warren, M.D. 9. "Correction by Operation of Some Nasal Deformities and Disfigurements," by George H. Marks, M.D. 10. "Formaldehyde Gas as a Disinfectant," by David D. Brough, M.D. 11. "The Pathology of Acute Infectious Osteomyelitis," by Edward H. Nicholas, M.D. 12. "The Shattuck Lectures, the Influence of the North American Climate on the People," by Sir William H. Hingston, M.D. The volume concludes with the proceedings, Councils of the Society and reports of the various officers. The articles are of a high class, and the volume shows that the advanced standing taken by the authors and the papers constitute marked additions to American medical literature.

The Care of the Baby, a Manual for Mothers and Nurses, Containing Practical Directions for the Management of Infancy and Childhood in Health and in Disease. By J. P. CROZER GRIFFITH, M.D. Second edition. Revised. Pp. 404. Philadelphia: W. B. Saunders, 1898. Price \$1.50.

The work is considerably larger than the former edition and is much improved. It has been completely revised and some new illustrations have been added. The work is designed particularly for mothers anxious to inform themselves with regard to the best way of caring for their children in sickness and in health, but is not intended in any way to take the place of the physician; indeed, the physician will find it of great service, as an aid to his efforts and in maintaining his authority.

A Manual of Venereal Diseases. By JAMES R. HAYDEN, M.D., with 54 illustrations. Pp. 304. New York and Philadelphia: Lea Bros. & Co., 1898.

This is the second edition, and, like all Gaul, it is divided into three parts, 1, being devoted to gonorrhea and its complications; 2, to the chancroid, and 3, to syphilis. There are nineteen chapters in the first part, two in the second and twenty-two in the third. It is concisely written and its teachings are sound. We regret to see that the old British system of weights and measures is adhered to in the prescription writing.

Hygiene of the Voice, with Twenty-seven Illustrations. By THOMAS F. RUMBOLD, M.D. Paper, 114 pp. St. Louis, Mo.: Witt Publishing Company, 1898.

The author states in his preface that his own experience teaches him not only that none but medical men should attempt the treatment of voice-users, but only specialists who have limited their practice to diseases of the throat, nose and ear should treat these diseases. This is not a book on treatment, per se, but a book which is intended to inculcate knowledge of the laws of vocal hygiene. Its teachings are wise and conservative.

The Essentials of Materia Medica, Therapeutics, and Prescription Writings. Arranged in the form of questions and answers prepared especially for students of medicine. By HENRY MORRIS, M.D. Pp. 288. Fifth edition, revised and enlarged. Philadelphia: W. B. Saunders, 1898. Price \$1.00.

We are pleased to see in this little volume that the metric system of weights and measures, has been introduced and that otherwise it has been revised and brought up to date. It follows closely the last edition of the United States Pharmacopeia and will be found very useful to those for whom it has been prepared.

The Pocket Formulary for the Treatment of Diseases in Children. By LUDWIG FREYBERGER, M.D., Vienna. Flexible covers. Pp. 208. London: Rebman Publishing Company, Limited, 1898.

In this "Formulary" prepared of the drugs used in the treatment of children, the names are arranged alphabetically, and the volume concludes with a therapeutic index. It will be found very useful as a remembrancer, and convenient for immediate reference.

Twenty-fifth Annual Session of the Florida Medical Association.—Paper. Pp. 161. Jacksonville: Vance Printing Co. 1898.

This volume comprises the papers and proceedings of the twenty-fifth annual session of this body, held at Jacksonville, Fla., April 26, 1898; also the constitution of this association and the Code of Ethics of the AMERICAN MEDICAL ASSOCIATION, with a list of members of the Florida Association. The volume lacks an index.

The American Pocket Medical Dictionary. Edited by W. A. NEWMAN DORLAND, A.M., M.D., Assistant Obstetrician to the Hospital of the University of Pennsylvania, etc. Containing the pronunciation and definition of over 26,000 of the terms used in medicine and the kindred sciences, along with over sixty extensive tables. Philadelphia: W. B. Saunders, 1898. Price \$1.25 net.

This is a handy pocket dictionary which is so full and complete that it puts to shame some of the more pretentious volumes. We commend it.

Tenth Report of the State Board of Health of the State of Maine. 1896-1897. Paper. Pp. 395. Augusta: Kennebec Journal Print, 1898.

This report is for the two years ending Dec. 31, 1897, contains a list of the members of the Board, the Secretary's report and two special papers, one a "Bacteriologic Report upon Formaldehyde," by Prof. F. C. Robinson and B. L. Bryant, and one entitled "Notes on Disinfectants and Disinfection," by the Secretary, A. G. Young, also printed separately and so noticed in the JOURNAL's book notices.

Pamphlets Received.

Abuse and Dangers of Cocain, The. By W. Scheppegegrell, New Orleans. Reprinted from Med. News.

An Additional Case of Double Congenital Microphthalmos; What Should the General Practitioner know About the Eye? By Cassius D. Westcott, Chicago. Reprinted from Journal American Medical Association and The Corpulse.

Annual Report of the Essex County Hospital for the Insane, Newark, N. J., Paper, illustrated. Pp. 72.

Arid Atmosphere of Our Houses in Winter, The. By Henry J. Barnes, Boston. Reprinted from Trans. Am. Pub. Health Assn.

Clinical Study of Interstitial Nephritis, with Methods of Diagnosis. By Everett J. Brown, Decatur, Ill. Reprinted from Med. Record.

Conservative Treatment of Fibroid Tumors by Myomectomy; Conservative Treatment of Pelvic Suppuration of Puerperal Origin; Operation for Restoration of Urethra and Closure of Vesico-Vaginal Fistula Involving Neck of the Bladder; Some of the Disadvantages of Vaginal Drainage for Pelvic Abscess. By Charles P. Noble, Philadelphia. Reprinted from Philadelphia Med. Jour.; Am. Jour. of Obstet., and Am. Gyn. & Obstet. Journal.

Contribution to the Study of the Muscular Dystrophies, a; Orchitis, or Epididymitis, as a Complication or Sequel to Typhoid Fever. By A. A. Eshner, Philadelphia. Reprinted from Am. Jour. of the Med. Sci. and Phila. Med. Jour.

Dangers of Specialism in Medicine, The; Manifestations of Syphilis in the Mouth. By L. Duncan Bulkley, New York City. Reprints from Bul. Am. Acad. of Med. and Dental Cosmos.

Deaths (Ten) Surgical and Causes; Dermal Coverings of Animals and Plants; Serpents and Their Venom; Copperhead, Coral and Rattlesnake. By B. Merrill Ricketts, Cincinnati. Reprinted from Lancet-Clinic.

Diseases of the Alimentary Canal; Treatment. By J. O. DeConcrey, St. Libory, Ill. Reprinted from Conr. of Med.

Effect of Hypertrophy of the Inferior Turbinal on the Nasal Septum. By Lewis S. Somers, Philadelphia. Reprinted from University Med. Mag.

Emotional Prodigality; Melancholia. By W. X. Sudduth, Chicago. Reprints.

Endemic Leprosy in Louisiana. By Isadore Dyer, New Orleans, La. Reprinted from Phila. Med. Jour.

Erosion of the Knee in Children, with Conservation of the Epiphyseal Cartilage; Preliminary Report on Treatment of Dislocation of the Hip by Operative and Manipulative Methods; Questions in the Treatment of Congenital Dislocations of the Hip; Scrobutus in Infants. Some California Cases; Traumatic Dislocations of the Hip in Children, Old and Recent. By H. M. Sherman, San Francisco, Cal. Reprints.

Flics as Spreaders of Sickness in Camps. By M. A. Veeder, Lyons, N. Y. Reprinted from Med. Record.

Individual Communion Cup and its Critics, The. By H. S. Anders, Philadelphia. Reprinted from Penn. Med. Jour.

Intravenous Injection of Normal Saline Solution. By H. T. Hanks, New York City. Reprinted from Am. Gyn. and Obstet. Jour.

Kryofin. By A. E. Minds, St. Louis, Mo. Reprinted from Tri-State Med. Jour.

List of Members of the Medical Association of the District of Columbia. Paper. Washington, D. C.

Modern Treatment of Tuberculosis. By Charles Denison, Denver, Colo. Reprinted from Journal American Medical Association.

My Name's Appendicitis. By Emma B. Standley, Alexis, Ill. Reprinted from Chicago Clinic.

New Treatment for Trachoma. By George F. Keiper, Lafayette, Ind. Reprinted from Ophthalmic Record.

Plan for Posterity. By A. L. Russel, Midway, Pa. Reprinted from Phila. Med. Jour.

Sleeplessness; Its Cause and Treatment. By E. S. Pettyjohn, Alma, Mich. Reprinted from the Phys. and Surg.

Two Cases of Fibroma of the Broad Ligament. By John C. Dacosta, Philadelphia, Pa. Reprinted from Am. Jour. of Obstet.

Trade Pamphlets.

Caroid. Am. Ferment Co., Jersey City, N. J.
 Catalogue No. 1. New York Med. Book Co., New York City.
 Illustrated Announcement. Harvey Med. College, Chicago.

 Hunyadi János Natural Purgative Water Drawn from Saxlehner's Bitter-Water Springs, near Budapest. Cloth. Illustrated. Pp. 113. Budapest: Andreas Saxlehner, 1898.

PUBLIC HEALTH.

An Official Warning.—C. A. Lindsley, M.D., secretary of the Connecticut State Board of Health, reminds his colleagues of the fact that during the last few weeks many soldiers have returned from the numerous military camps, convalescent from typhoid fever or taken down with it after their return. Each of these cases is a source of further infection unless the precautions, which are now so well known and so effective, are carefully and scrupulously observed. The infective agent is a living germ, which is thrown off in great abundance from every typhoid patient, with the excretions from his bowels and kidneys. The immediate destruction of these germs by some disinfectant is the only means of safety. The importation of so many cases into the State, and their wide distribution in various places, will be very likely to cause additional local outbreaks of the disease if vigilant and unremitting attention is not given to the thorough disinfection of the discharges from the patients and whatever of the bedding or clothing may be soiled by them. Circulars on the means of preventing and restricting typhoid fever will be sent freely to any persons on application. The sickroom should have in it only sufficient furniture for use and comfort; no carpets, tablecloths, pictures, draperies or ornamental hangings. The practice of suspending towels and sheets about the sickroom, saturated with carbolic acid and other odorous solutions, cannot be commended. It has little other effect than to frequently cause nausea and headache in the patient and attendants. The mattress should be protected by an impervious rubber sheeting under the usual bed sheets. Two or more will be necessary, so that they can be changed and cleaned as required. The rubber sheet should be thoroughly sponged with carbolic solution, then dried and aired in the sun for several hours. The body- and bed-linen should be changed daily. Never shake them. As soon as removed immerse them in a disinfecting solution composed of carbolic acid and water, 1 part to 40, or in a bichlorid of mercury solution, 1 part to 1000. Let them soak four hours or longer, then boil them for half an hour and wash with soap. All food brought into the sick-room and not consumed by the patient should be burned. The nurses should wash their hands whenever they may have become soiled by handling the patient or the clothing, and always before eating or leaving the room. The same rule should be observed by the physicians and other attendants. The importance of extreme cleanliness of the hands of the patient might be added as a means to the prevention of those relapses of fever that are the result of autoinfection. During the prevalence of typhoid, it is prudent to boil all the drinking water and all the milk. When such attention is given to disinfection, rigid isolation is not necessary; and when disinfection is neglected, isolation will be of little importance.—Circular No. 75, 2d edition.

Heavy Mortality by Plague in India.—About two years have passed since the plague became epidemic in the Bombay district, and in that time over 105,500 deaths, or an average per month of 4400 deaths have been admitted to have occurred. In addition to this huge total there have been many thousand deaths from the plague that have been registered as from other febrile causes. In one week in September, this year, in the Bombay Presidency, there were reported 3635 cases and 2749 deaths by plague. In Bombay City, the last week in September, there were 209 deaths, as compared with 127 in the week previous. In Bombay Presidency the number of deaths increased from 3000 in the previous week to 4000, chiefly in Dharwar, Belgaum, Satara and Kolhapur. Calcutta is free, and only one death is reported from Karachi, but the plague is becoming epidemic in Bangalore city, where 124 deaths have occurred.

Three cases are reported from Hyderabad State, three from Wallunden in the Punjab, and sixteen in four districts of Madras. The editor of the London *Lancet* makes the following comment: "The quarantine and severely repressive measures which have been favored hitherto have, as we all know, given rise to a great deal of native discontent and opposition, and as they have not been attended with the successful results which were anticipated or hoped for, the Government of India has had to relax them. The progress of the epidemic in India is conforming to what has been the history of plague elsewhere in the past and in China, the enforcement of land quarantine is attended with serious hardships and is moreover, simply impracticable; the natives would prefer to run the risk of contracting plague to submitting to the severely repressive measures hitherto enforced. As a matter of policy the government is justified in relaxing them under the circumstances in which it is placed. With regard to inoculation, remarkable success is reported from Hubli, and it is stated that no less than 32,000 people have gone through the process. During the existing outbreak in that city only sixty-nine of these have been attacked, while among 8500 uninoculated there have been 417 attacks. If these figures be reliable they speak for themselves. In the district around, however, there have been a large number of deaths, the Dharwar district, in which Hubli is situated, being credited with 1047 cases and 892 deaths. To show how differently inoculation has been received at different places there remains only to compare Calcutta and Bombay, each with about 750,000 inhabitants and about 2000 and 20,000 persons inoculated respectively, against Hubli, with a population of about 40,000 and no less than 32,000 inoculations. In Bombay there have been 27,305 deaths from plague, and in Calcutta about 200.

Trichinous Pork Products in Germany.—During the fifteen years beginning with the decree of 1883, forbidding the importation of American meat into Germany, the latter country has official knowledge of 3003 cases of illness due to trichinæ, with 207 fatalities. Of these there were 1242 cases, or 41.3 per cent. of all, traced to European pork; deaths by this cause 102, or 49.7 per cent. of all. The remainder was due to a variety of sources, but in not one of these 3003 was it proven that the illness was caused by the use of American salted, pickled, or tinned meat, nor by smoked sausage imported under imperial decree of 1891. This statement holds good for all Germany. In confirmation of this fact, a society of importers of meat hereinbefore mentioned has issued posters wherein a reward of \$238 is offered to the person who can prove that trichinæ have been transferred to human beings by the consumption of American salted or pickled pork or smoked sausage imported under the imperial decree of 1891, canceling the edict forbidding the importation. The inspection of American meats and sausages is much more rigid than the tests for the German home products. The American product is twice inspected. Before the meat leaves the United States, from each hog, as a whole, the inspector selects six samples or pieces, and from these pieces are taken eighteen cuts, to which is applied the microscopic test. When this meat reaches Germany it is again cut into eight or ten pieces; from each of these the inspector selects three samples or pieces, and from each of these samples or pieces three are taken for the microscopic test. This results in the inspection of ninety separate pieces from the American hog, while in the inspection of the German hog only eighteen pieces are tested. It is reported that uninspected American hog products have been introduced into Germany from Belgium, in boxes in which other regularly inspected meats had been received from America, bearing the label of microscopic inspection. Originally, in the microscopic inspections in the United States, the certificates thereof were the same as those given for usual ante and postmortem inspections, with the addition of a red stamp placed on the certificate stating that the goods mentioned were microscopically inspected and found free from trichinæ. On one occasion a carload of bacon arrived at the custom-house of Aix la Cha-

pelle, the certificate of which was without the red stamp. The customhouse officers refused to let the car enter Germany and reported the case to the buyer at Düren. This man wrote to the Antwerp firm that he refused to accept said car, because he was entitled to receive the meat regularly inspected as required by the German laws. The seller at Antwerp replied that, in fact, the meats in question had been regularly inspected microscopically, and it was by mistake that the certificate did not bear the red stamp; that such an error happened sometimes, but that the United States consul in Antwerp would rectify the certificate if the buyer would return it for that purpose. Unfortunately for the Düren merchant, he believed this story, sent the certificate back, and received it again two or three days afterward bearing now the red stamp. He presented this document at the custom-house at Aix la Chapelle, in order to have the carload entered into Germany; but the custom-house officer had reported first to the American consul at Antwerp, and when he learned that the consul had neither changed the certificate nor been authorized to do so, the entrance into Germany was refused and the buyer placed under accusation of having falsified a public document. After several years, the suit terminated in the Supreme Court at Leipzig with a sentence of the Düren merchant to eight days' imprisonment for assisting in the falsification of a public document. The Belgian merchant, of course, could not be prosecuted in Germany. How many times the Belgian port has sent into Germany uninspected meats, it is impossible to say. It is rumored that a regular traffic in empty boxes with proper inspection labels and certificates has existed in Antwerp for some time, with a probability of a like organization in Rotterdam.—"Consular Reports," October.

SOCIETY NEWS.

Tri-State Medical Association.—At the annual meeting of this Association, at Birmingham, Ala., the following officers were elected and Chattanooga, Tenn., chosen as the next place of meeting: President, George A. Baxter, Chattanooga; first vice-president, M. C. McGammon, Nashville; second vice-president, W. D. Travis, Covington, Ga.; third vice-president, George S. Brown, Birmingham; secretary, Frank Trester Smith, Chattanooga; treasurer, Cooper Holtzklaw, Chattanooga.

Iowa State Association of Railway Surgeons.—At the annual meeting held in Clinton, October 13 and 14, the following officers were elected for the current year: President, H. L. Getz, Marshalltown; vice-president, A. L. Wright, Carroll; treasurer, C. B. Powell, Albia; secretary, Ira K. Gardner, New Hampton. Ottumwa was selected as the next place of meeting, October, 1899.

Washington, D. C., Medical Society.—The meeting of the society on the 2d inst. was called to order by the president, Dr. Busey, in memorial of the late Dr. Lincoln. Dr. J. Ford Thompson, chairman of the committee, read the resolutions of respect and condolence which had been prepared, and on motion they were adopted. Dr. I. C. Rosse read a memorial notice of Dr. Lincoln, and eulogistic remarks were made by Drs. Lovejoy, Makall, Loering, Murray, Godding, W. W. Johnston, Mary Parsons, and Morgan.

Detroit Academy of Medicine.—At the regular meeting, October 25, Dr. E. H. Troy read a paper on "Cholera Infantum." He thought the bacteriology of the subject is in such confusion, little can at present be said on the subject, except to affirm that such violent vomiting and purging as always occurs in true cholera infantum can result only from the poisons produced by most virulent germs. Such large, watery movements must result from severe depression to the central nervous system. Hence the study along this line had been made in regard to treatment. Two drugs were advocated for their effect: the one on the central nervous system, and the other for its effect upon the nerve endings in the intestines, viz., chloral hydrate and dilute hydrocyanic acid, these had been given in small doses frequently repeated, and their action carefully noted. In addition, enemata of normal saline solution

had been used frequently repeated. Under this treatment better results had been secured than with the older methods. In the discussion it was stated that the lessened number of cases of cholera infantum in Detroit now as compared with twenty-five years ago is as much due to improved sewerage and pavements as to the improved methods of feeding infants. Further, the presence of the island park and the more extensive use of the Detroit River by the poorer classes has been a most potent factor in keeping the mortality down to its present level.

Washington, D. C., Medical and Surgical Society.—The society met on October 31, in celebration of its decennial. Dr. Lewlynn Elliott, the president of the society, opened the exercises with an address, in which he outlined the history of the early formation of the society, tracing its growth during the past ten years and referring to the valuable papers and discussions by the different members. He also referred to the future work and the good they might accomplish in the future of medicine and hygiene. Dr. Landon B. Edwards of Richmond, Va., discussed the benefits of medical examining boards to the community and the medical profession. Dr. W. W. Johnston read a paper on the relation of health to education, based on his observation and study of the early education of children, and Dr. George M. Krober read one entitled "Higher Medical Education, and a Plea for Better Training for the Volunteer Medical Officer." He touched upon the losses of the army in the war with Spain, and praised the Surgeon-General's conduct of his department. He suggested that the medical colleges should pay attention to the line of work which would fit physicians especially for military service, and he called special attention to the excellent equipment and the facilities offered by Washington for the study of medicine, asserting that the many advantages were not fully known to many members of the medical profession. The meeting closed with a banquet at which Dr. Elliott presided. Toasts were responded to by Drs. Stone, Kelly, Kober, Edwards, Alden, Woodward, Bishop, Massen and Morgan.

Southern Illinois Medical Association.—The program of the meeting to be held in Cairo, Ill., Nov. 17 and 18, 1898, includes: "Influence of the Climate of New Mexico in the Treatment of Diseases of the Chest," by Wm. Curtiss Bailey, Las Vegas Hot Springs, N. M.; "Typhoid Fever—A Case with Unusual Manifestations," by A. M. Lee, Carbondale, Ill., discussion led by J. W. Armstrong, Centralia, Ill.; "Report of Two Cases of Hydrophthalmos," by James Moores Ball, St. Louis, discussion led by A. C. Corr, East St. Louis, Ill.; "Typhoid Fever in a Country Practice," by S. P. Schroeder, Hazleton, Ill., discussion led by C. W. Sibley, Fairfield, Ill.; "Sanitation and State Medicine," by A. C. Corr, East St. Louis, Ill., discussion led by J. W. Pettit, Ottawa, Ill.; "Some Reminiscences of the Southern Illinois Medical Association," by H. Wardner, Laporte, Ind.; "Paretic Dementia," by F. Samuel Dodds, Anna, Ill., discussion led by H. C. Hall, Omaha; "Some Practical Observations in Typhoid Fever," by H. V. Ferrell, Carterville, Ill.; "Case of Compound Dislocation of Knee-Joint Complicated with Compound Fracture of Same Femur Above the Condyles; Leg Saved by Means of Hodgen's Splint," discussion led by Chas. H. Starkell, Belleville, Ill.; "Medical and Surgical Treatment of Renal Calculi, with Report of Seven Cases," by H. C. Mitchell, Carbondale, Ill., discussion led by Dr. Bransford Lewis, St. Louis; "The Importance of Early Operation in Cholelithiasis," by A. H. Meisenbach, St. Louis, discussion led by J. H. Mitchell, Mt. Vernon, Ill.; "Some Neglected Signs in Gynecologic Examination," by Jno. A. Hale, Alto Bass, Ill., discussion led by B. F. Crebbs, Carmi, Ill.; "Ectopic Gestation—Diagnosis and Treatment," by J. L. Wiggins, East St. Louis, Ill., discussion led by H. H. Mudd, St. Louis; "Rectal Diseases—Its Surgical Treatment," by Phil. H. Stewart, Paducah, Ky., discussion led by Leon Strauss, St. Louis; "Peritoneal Abscess Simu-

lating Fibroid Tumor," by H. J. Welsh, Cairo, Ill., discussion led by H. C. Gault, Sparta, Ill.; "Personal Experience in Operating with the Use of Infiltration Anesthesia," by Louis T. Riesmeyer, St. Louis; "Ventre-Fixation for Retroversion," by George Wiley Broome, St. Louis; "Circumcision," by Wm. A. James, Chester, Ill., discussion led by H. C. Fairbrother, East St. Louis, Ill.

NECROLOGY.

J. D. AMES, M.D., Dekoven, Ky., aged 80 years, October 31. —Peter H. Brooks, M.D., Lima, Ohio, October 28. —J. W. Davis, M.D., Smyrna, Tenn., October 31, aged 77 years. —Roswell Fox, M.D., Wethersfield, Conn., October 26, aged 73 years. —S. E. Givan, M.D., Burney, Ind., October 25. —J. H. Head, M.D., Centralia, Mo., October 29, aged 58 years. —B. H. Paschall, M.D., Arrington, Tenn., November 1, aged 73 years. —David Randall, M.D., Morrisville, Vt., October 25. —Albion P. Snow, M.D., Winthrop, Me., October 25, aged 69 years.

DEATHS ABROAD.—Professor Bouchacourt of Lyons, France, author of numerous works on obstetrics and gynecology, hydatidic and hydatiform degeneration of the kidneys in the fetus, etc., 87 years of age. —Dr. Heydenreich, professor of clinical surgery at Nancy, France; H. Spöndli, formerly professor of obstetrics at Zurich; D. Toscani, professor of legal medicine, Rome. —Dr. Slawiansky, professor of gynecology at St. Petersburg.

MISCELLANY.

Through a typographical error the name of Prof. Nicholas Senn was omitted from his War Correspondence (see page 1164.)

Renal Surgery.—Bazet of San Francisco, in a paper on the "Advances in and the Present State of Renal Surgery" (*Phil. Med. Jour.*, October 22), reduces the conditions calling for operation in renal lithiasis, to three: 1, calculus in a healthy kidney; 2, calculus in a diseased kidney; 3, anuria. In the second condition, lesions due to aseptic calculi are characterized by sclerosis or hydronephrosis, and he considers removal of the organ by immediate nephrectomy most logical in the former, while calculus hydronephrosis requires conservative treatment, the kidney, "though thinned and disturbed" being still useful, primary nephrectomy being advised "only when the renal pocket is enormous and the parenchyma is reduced to the thickness of a thin sheet of paper;" otherwise nephrotomy is the operation to be selected, and is preferable in septic lesions with or without distention. Anuria calls for immediate operation.

Pharyngeal Adenoids.—Delavan (*N. Y. Med. Jour.*, October 29) emphasizes thoroughness and humanity as the two essentials to success in operative treatment of this condition. Atrophy of the remainder, after partial removal of an adenoid growth, he considers the exception; rather, the tissue remaining, being unhealthy, is likely to remain so, and may cause life-long annoyance to the patient or injury to surrounding parts. He considers in detail the various methods of removal and the anesthetics of use, advising complete anesthesia to secure ideal conditions for operating, and the blunt forceps for the most thorough removal.

Infective Nature of Eclampsia.—Professor Stroganoff asserts that eclampsia should be included among the infective diseases, giving as his reasons: 1. That it is a general disease, affecting all the parenchymatous organs. 2. That it is an acute affection, commencing explosively or after a certain prodrome. 3. The fever that accompanies it occasionally, especially the postmortem thermic elevation peculiar to an infective disease. 4. One attack confers immunity. 5. The marked genus epidemicus; in 1897 25 per cent. died, while in nineteen cases this year there has been no mortality. 7. It is impossible to explain the increase of eclampsia in populous centers other-

wise than by accepting the theory of its infective character, which he is now seeking to prove definitely. His communication in *Wratsch*, Nos. 26 to 35, contains tables showing the links in a number of series.

The Heart.—V. Frey ascribes the rhythmic action of the heart to the muscles, remarking that every bit of the heart, whether it contains a ganglion or not, is capable of automatic activity. The rhythmus is more rapid and less disturbed by extraneous influences, the nearer to the venous portion of the heart, which imposes its rhythm upon the whole. The nerves of the heart are largely centripital, serving for the important reflexes on the organ, respiration and lungs. The centrifugal nerves affect the normal muscular rhythm and peristalsis by altering the number and vigor of the contractions or the transmission of the impulse. Trophic nerve action has not been established nor the co-operation of the ganglion cells in any of the functions of the heart. He estimates the volume of the beat as much less than formerly assumed. The probable quantum in man is 50 to 60 c.c. The work of the heart is extremely dependent upon external conditions, such as pressure of other organs, etc., and modern science possesses means to determine these variables, at least on the isolated heart, which opens new points of view for the study of medicinal substances. —*Cong. of Germ. Nat. and Physicians.*

Murmurs of "Mitral Insufficiency."—Dr. C. F. Hoover in the *Cleveland Medical Journal*, states that in his experience there is a difficulty demonstrating a genuine mitral insufficiency. The regurgitation of the mitral wave is not visible. A curious inconsistency between the causes and occurrence of murmurs is in the fact that we do not always have the murmur when a valvular insufficiency is present. The fact that we can demonstrate a dilatation of the right ventricle and see a positive venous pulse, to my mind, shows the presence of a genuine tricuspid regurgitation. In spite of this we sometimes have these conditions without any murmur at all over the right side of the heart. He believes cardiopulmonary murmurs occur more frequently than many would concede. Often murmurs associated with acute dilatation can not be endocardial in origin. A young man with an acute infection came to the hospital with an increased precordial dulness, with a very distinct thrill over the apex. Percussion shows that the apex is covered by a tongue of lung. If this patient would make a forced expiration the heart would become more exposed, as you can show by palpation and percussion and the thrill and murmur entirely disappear. This patient has an acute dilatation; nevertheless, when there is no lung intervening between the heart and chest-wall, the murmur is not audible. Another point is the time of this murmur. It occurs during the first portion of the anteroposterior excursion of the heart. Dr. Stengel suggests the production of a murmur occurring in relative insufficiency in this way, viz., that the contraction of the papillary muscles produces a genuine mitral insufficiency. If we accept the interpretation of the heart's impulse and the rôle of the papillary muscles in the cardiac activity, as given by Roy and Adami, we should always hear such a murmur at the end of the anteroposterior excursion of the heart. Experience shows that in a very large proportion of the cases of relative insufficiency of the heart the murmur is heard during the first portion of the anteroposterior excursion. I believe there is such a thing as a genuine murmur of relative insufficiency due to the dilatation of the mitral ring. But my experience in the murmurs of relative insufficiency accompanying acute dilatation leads me to believe that they are very frequently pulmonary and not endocardial in origin.

Acute Fatal Pancreatitis.—In temperate climates acute pancreatitis is so seldom met with that it is a curio even among pathologists. We note in the *Lancet* that a case has been reported lately from Hong Kong, one of the papers of that city

containing an account of an inquest held upon the body of the ward-master of the Government Civil Hospital, who was found dead in his quarters at the hospital on March 17. Dr. Atkinson, the principal medical officer, in his evidence said that he was summoned in the afternoon to see Mr. Feltham. He found him lying dead on the sofa. At the postmortem examination made on the following day, at which he was present, the cause of death appeared uncertain and the stomach and contents were handed over to the government analyst. The government analyst, deposed to examining the contents of the deceased's stomach: it contained nineteen grains of chloral and one-third grain of morphia. He had last seen deceased alive at midday on the 17th. Dr. Lowson, who made the post-mortem examination, deposed to finding acute inflammation of the stomach and pancreas; in the head of the latter there was a large hemorrhagic extravasation. The condition found could not have been caused by either chloral or morphia and in all probability the deceased could not have taken more than thirty grains of chloral, for the absorbing powers of the stomach must have been considerably impaired. The cause of death was syncope in acute gastritis and pancreatitis possibly accelerated by a medicinal dose of chloral. The presiding magistrate gave his finding in accordance with this evidence.

Tuberculosis Pulmonum Traumatica.—Dr. Schrader of Berlin has advanced the opinion that trauma is a cause not only of acute pneumonia, but also of chronic pulmonary disease. He relates the following case: A man, aged 29 years, previously healthy, and with no family history of phthisis, had a severe fall on the right side of the back, and was unconscious for fifteen minutes. On the same evening he felt ill, and was admitted into the hospital two days after the accident. There was then considerable grazing over the right scapula, and pain was complained of in the chest corresponding to the injured part. The breathing was difficult and the temperature 38.8 degrees C. The breathing sounds were absent, vocal vibration increased, and the percussion note impaired in the region underlying the injury. The diagnosis of pneumonia of the right middle and lower lobes was eventually made. About thirteen days after the accident tubercle bacilli were found in the sputum. The patient's condition remained much the same for some days. There was loss of weight. Eventually improvement took place, so that four months after the accident there were no abnormal physical signs beyond a slightly impaired note over the lower part of the right lung. The author refers to some recorded cases of supposed phthisis following injury. He draws attention to the fact that before traumatism the patient was absolutely well. Whether the pneumonia following the injury is to be looked upon as a contusion pneumonia which favored the invasion of the tubercle bacillus, or whether it was a tuberculous bronchopneumonia from the beginning, it is difficult to decide. The author is inclined to accept the latter interpretation. The temperature chart was characteristic of tuberculosis. Finally, the author summarizes the evidence in favor of this view: 1. The development and course of the tuberculous lesion were carefully observed after the accident; 2, the disease corresponded to the site of the injury; 3, there was no clinical evidence of tuberculous disease in the lung immediately after the injury, and no history of previous illness; 4, certain proof of tuberculosis was forthcoming some little time after the accident, the development of which was quite in keeping with that of the ordinary disease.—*British Medical Journal*.

Physiologic Albuminuria.—Herter, before the New York Academy of Medicine, recently (*Phila. Med. Jour.*, October 29) emphasized the fact that when certain delicate tests for albumin are employed, there is serious danger of calling substances albumin that have an entirely different origin and significance. He considers the cold nitric and potassium ferrocyanid tests,

though not entirely free from this objection, used with the heat test, the most practicable means of recognizing albumin. Where these tests fail to disclose albumin in the urine, which may be found by other reagents, the patient may be assured that he has no albuminuria, and "albuminurias that can not be recognized by the three tests mentioned are only important as material for erroneous practical conclusions, and have no interest for the practitioner."

Chloroform Anesthesia.—Before the recent meeting of the American Laryngologic Association, Hinkel (*N. Y. Med. Jour.* October 29) reported a case of death immediately following an operation for nasopharyngeal adenoids, chloroform being the anesthetic used. In addition he gives other statistic and pathologic data, showing an abnormally high mortality from such anesthesia "for the removal of lymphoid hypertrophies of the pharynx," and that the "general use of chloroform in the operations for hypertrophied tonsils or nasopharyngeal adenoids is inadmissible."

Massage in Italy.—The *Gazz. degli Osp.* states that massage is in high favor at Giappone, where it is practiced as regularly as the Turks perform their ablutions or the Chinese smoke opium. From the humblest street peddler to the "upper ten," the masseur is summoned when the day's work is over, and in spite of the humidity of the climate, the people of Giappone are exempt from a number of the ills that flesh is heir to, which afflict the dwellers in other towns. The massuers use for superficial manipulations a heavy wooden ball set in another ball, which they grasp and knead the tissues by pressing and rotating. A similar device was described in the *JOURNAL*, Vol. xxvii, page 270.

Pasteur Institutes.—The Berlin correspondent of the London *Lancet* writes that after having absolutely refused for more than ten years now to put any faith in the Pasteur treatment for rabies, the Germans have at last resolved to try it. An appropriation for an experimental station for the treatment according to Pasteur's method is one of the items in the medical budget for the year. It is to be carried on in connection with the Institute for Infectious Diseases, Professor Koch's department. Though it is said to be only experimental, it would seem as though this was scarcely more than a half-hearted apology for the refusal to have had anything to do with it before. The treatment itself is far beyond its tentative stage, and each year brings more and more encouraging statistics as to its results in Russia, in Italy, in India and in Egypt. The bacteriologic laboratory which was founded by Pasteur at Constantinople by request of the Sultan, has recently reopened its doors after a long period of idleness due to an alleged indifference and carelessness of the State officials, and to lack of funds. The French charge d'affaires protested, as did the Imperial Society of medicine, and in this way the attention of the Sultan was drawn to the precarious state of an institution in which he had taken the greatest interest. It is probable that the work of the institution will be greatly developed, for orders have been given that the director of the institute shall want for nothing.

Tetanus.—Stintzing has established, on animals, that the tetanus bacillus generates toxins at its entering point, which may pass into the circulation to some extent, but are mostly carried along the nerves in the neighborhood to the subarachnoidal space or spinal cord, from where they produce their effect, starting from the entering point, spreading later into general tetanus, which occurs more rapidly in man, owing probably to the larger size of the channels of transmission. The points particularly attacked by the toxin seem to be the motor ganglion cells in the anterior cornua. He states that 96 cases of tetanus have been treated to date with Behring's serum, with 35 deaths, but only in 15 cases was the serum given as Behring insists, not later than twenty-six hours after the com-

mencement of the attack. Ten out of these fifteen died. Krokiewicz has injected an emulsion of brain matter in salt solution in one case, with prompt recovery. Vincenzi has recently demonstrated that the bile of tetanized animals possesses antitoxic properties. Escherich reported six new cases of "pseudo tetanus," first described by him at Moscow, characterized by persistent, typic tonic contractions and trismus, which run their course without fever and recover in a few weeks.—*Cong. of Germ. Nat. and Physicians.*

Concussion vs. Intoxication.—Dr. L. D. Mason, in the *Brooklyn Medical Journal*, instances one of those deplorable cases to which attention has been frequently called in the JOURNAL, where the police imprison an injured person under a station-house diagnosis of drunkenness. It was one of those night cases where a bicyclist was struck by a trolley-car and suffered from temporary confusion of thought as a result of the injury. A roundsman and sergeant of police, in order to save time and bother, took upon themselves the responsibility of not calling in medical advice and locked up the innocent and dazed but sober gentleman for the night. In other words, both insult and injustice were added to injury. It was not long ago that one of our leading medical societies appointed a committee to investigate concerning the care of persons who were found unconscious on the street or elsewhere by the police, and also more particularly to reform the action of the hospital authorities concerning the reception or refusal to receive all such persons, under certain conditions. The conclusions that the special committee finally arrived at after considering the whole matter from a scientific and humane standpoint, was that all persons found upon the street in an unconscious or semi-conscious condition, or in such condition as not to be able to care for themselves, should receive prompt medical aid, and if necessary be removed to the nearest hospital, and that the mere supposition of intoxication should not interfere with such care or disposal of the persons rendered unconscious or unable to care for themselves. The committee showed that not unfrequently persons were seriously injured while intoxicated, and that frequently alcoholic liquors were given to persons after injury or sickness; so that the mere fact that the patient was under alcoholic influence should not exclude the possibility of serious injury or disease. The fact was that the injured person was suffering from slight cerebral concussion, resulting in confusion of thought and simulating a mild form of alcoholic intoxication. It was simply a case of mistaken diagnosis on the part of the roundsman doctor and the sergeant who acted as consulting surgeon in the case. The remedy, a night in the lock-up, was rather severe and totally uncalled for. An innocent injured man was punished with false imprisonment in consequence of his injury. The system is a wrong one that put the roundsman in the position to differentiate between cerebral concussion from a trolley-car accident and a mild form of alcoholic intoxication. If this presumptuous policy for the police is to persist, it may be well to suggest that a new question be answered by all applicants for the police force, in accordance with the rules governing the civil service examination: "What are the main points in the differential diagnosis between moderate cerebral concussion, and consequent mental disturbance, and the milder forms of alcoholic intoxication?"

Improved Ear Trumpet.—Kugel of Bucharest has designed a trumpet on the principle of the ear of the horse, like which it is shaped, instead of the usual large flaring rim, to concentrate the sounds. This shape obviates the annoying resonance of the ordinary trumpet, especially as there are a number of holes pierced in the conducting tube. Gruber and Politzer endorsed the new trumpet at a recent meeting of the Austrian Society of Otology. Bing also suggested that as the sounds collected by the receiver are all transmitted to the ear together, instead of being concentrated as when light is focused, the

tube that conveys the sounds from the receiver to the ear should be as large as possible, with no space wasted. He therefore suppresses the tube altogether and applies the receiver directly to the entrance of the auditory canal, thus securing a fuller tone, and intends to supplement the instrument with a hollow plate over the mastoid apophysis, to promote osseous conductivity.—*Rev. Hebdom. de Laryng.*, October 8.

A Needle-Swallowing Epileptic.—Dr. Charlton Bastian has reported a case communicated to him by a physician at Guieborough, who stated that eighty six needles and one pin had been removed from the patient, a female inmate of the workhouse there. Fourteen others were still to be felt in different parts of the left side of the body. Of these needles, seven are very large, ranging from three and one-fourth to three and three-fourth inches in length. The patient is now 55 years of age, and has been subject to fits from early childhood. She was admitted into the workhouse in 1886. She sometimes had several fits in one day, and rarely passed a day without having one. She recovered quickly from the attacks, and nothing like a post-epileptic automatic state had ever been recognized. She was described as fairly intelligent, but as having fits of bad temper, in which she refused to do anything except knitting, and would not take her food. She had no morbid appetites, and her conduct toward others had been on the whole satisfactory since her admission. Needles were first noticed in her body after she had been in the workhouse about twelve months, during which time she had been accustomed to do much sewing, and often had packets of needles in her possession. The needles had all been extracted by the doctor, the nurse, or the matron, or else by the patient in the presence of one of them. With the exception of one needle expelled from the mouth during a fit of coughing, all had been extracted from some part of the left side of the body, principally from the hypochondriac, lumbar, and iliac regions, or from the buttock and the thigh. No abscesses have occurred in connection with the presence or passage of any of the needles, nor had wounds of vessels or great nerves ever been produced. The patient was not distinctly hemi-anæsthetic, though there did seem to be some blunting of sensibility on the left side of the body. She had never been seen passing needles into her body, nor would she make any definite statements on the subject. She had complained very little of pain from the presence of needles in her body, but of some irritation and tenderness when they were approaching the skin and were about to emerge. The needles then caused some slight inflammatory redness, and often some induration of the tissues immediately around them, but no suppuration. The sites from which needles had been extracted were indicated by small white scars. This strange needle-cushion-like patient had apparently had nothing to gain by thus torturing herself in so extraordinary a manner.

Plumbers Examined as a Health Measure.—Under modern systems of house building and disposal of sewage, the dangers to the health of the entire public, arising from defective plumbing, are so great, and at the same time so insidious, that were the State unable to provide for the proper regulation and supervision of the plumber in his work, so as to minimize the danger to the public health from the escape of sewer gas, the supreme court of Wisconsin well says that the State would certainly be unable to protect the public life and health in a most important particular. This power, it adds, may be exercised by the legislature by demanding practical knowledge of his business on the part of the plumber, or it may be done by requiring inspection and supervision of his work by experts, or by both means combined; and, when such regulations are brought before the courts, the question simply is whether or not they are really appropriate and reasonable measures for

the promotion of the public health and safety, and hence are a valid exercise of the police power. For example, the court holds, in the case of *State vs. Bezenberg*, Sept. 20, 1898, that a law is not unreasonable when it requires that a master or journeyman plumber shall be examined as to his practical knowledge of plumbing, house drainage, and plumbing ventilation, all of which may be acquired in the school of actual experience, while assisting a practical plumber at his work, it not being anticipated that more than this practical knowledge will be required by any examining board. But the court, at the same time, holds that chapter 338 of the Laws of Wisconsin for 1897, entitled "An act relative to the licensing of plumbers and the supervision of the business of plumbing," is void, as discriminating between persons under the same circumstances and conditions, the discrimination being in favor of firms and corporations as against a plumber doing business alone, because it would permit several plumbers to form a partnership or corporation, and all engage in practical plumbing, when only one of their number had obtained, or perhaps was able to obtain, a certificate of competency.

Not Liable for Use of Impure Vaccine.—A municipal corporation, while enforcing a valid ordinance requiring citizens and residents of the city to submit to vaccination, is exercising a governmental power, and, the supreme court of Georgia holds, in the recent case of *Wyatt vs. the City of Rome*, is therefore not liable to a citizen who may sustain damage on account of impure vaccine matter administered to him by one of the officers or agents of such corporation. To allow any citizen a right of action on account of injuries, real or supposed, that he may have suffered in the interest of the public good, the court says, would be to paralyze the arm of the municipal government, and either render it incapable of acting for the public weal, or would render such action so dangerous that the possible evil consequences to it, resulting from the multiplicity of suits, might be as great as the smallpox itself. Hence, the wisdom of the law in exempting it from liability on such an alleged injury as one resulting from the negligent administration of impure vaccine matter by the officers or agents of a city while enforcing a valid ordinance. The right to prescribe regulations looking to the preservation of the public health, further says the court, is one of those sovereign powers that belong to the State. This power can be delegated by the State to any of its subdivisions of government, such as a municipality or a county, and in the use of it by such subdivisions they are in the exercise of a function purely governmental. When a municipality exercises a governmental power conferred upon it by the State, it is just as if the State itself were in the exercise of the function thus conferred. And it is upon the idea, as old as the English law—"the king can do no wrong"—that the sovereignty of a State protects it against suits by its subjects; no one having a right to hold it liable for any of its officers or agents, unless such right is expressly granted by the State itself. Among the precedents which have been established by courts of last resort that are apparently exceptions to this general rule, the supreme court of Georgia says it has been able to find none that would hold a city liable for any injury that may be sustained as the result of enforcing measures legally enacted for the promotion and preservation of the public health.

Professional Secrecy.—The *Klin.-therap. Woch.* of October 9 describes a case in which a physician was consulted in regard to the health of a daughter whom he found pregnant, but considering himself bound to professional secrecy, he diagnosed the case to the parents as anemia. The parents later ascribed the paternity to him in spite of the girl's declarations to the contrary, as the only possible explanation of his reticence.

Disreputable, but not Larceny.—That Francis M. Steward was convicted of larceny, in the criminal court of Cook County,

the supreme court of Illinois holds, in the reversed case of *Steward vs. People*, was error. According to the statement of the case made by the supreme court and the evidence for the State, the defendant in the criminal court was a doctor, in Chicago; Herman Klepstein was a shipper of a carload of live stock that came to the city, and Timothy Englehard was a person in the habit of bringing patients to the defendant, and receiving some compensation for doing so. Klepstein fell in with Englehard, who after a little time, asked him what was the matter with him, saying that he looked sick. When they got down town, Englehard said that he had to go to the defendant's office to get some medicine for his baby. He persuaded Klepstein to go into the office, and spoke to the defendant about medicine for his baby, and then introduced Klepstein and said that he looked sick, that his eyes looked bad. After the introduction the defendant told Klepstein that he looked sick, but he replied that he was not sick. Then the defendant said that he was a professor, and could tell when people were sick, but could not tell what was the matter until he made an examination. He and Englehard told Klepstein to pull off his overcoat, etc., and one or both assisted him more or less. After the examination which followed, the defendant told Klepstein that he had heart disease, brain trouble and piles; demanded \$150 for the treatment said to have already begun; finally took a draft for \$50 and a note for the balance; wrote out a prescription and all went to a drug store, where the prescription was filled, Klepstein paying \$3.75 for the package of medicine handed to him, and telling a clerk about the arrangement for treatment and that he was afraid the Doctor would not cure him. The note Klepstein got back later, and he admitted that at the time of the examination he told the defendant that he would deposit \$200 if he would make him as strong and healthy as he was when he was 17 years old, but that the defendant said that he could not do that. A thorough examination made by another physician, ten days later than the one just mentioned, developed nothing of any consequence in the way of disease, but seemed to show that, on the whole, the man was in good condition and health. Now, while under these circumstances, the defendant was convicted of the larceny of the draft for \$50 from Klepstein, the supreme court holds that larceny was not committed, no matter what else it might be, because the crime of larceny always includes the taking and conversion of property without consent of the owner. It says that the methods employed were disreputable, and that Klepstein was over-persuaded and induced to do what he would not otherwise have done; but that there was no larceny, because Klepstein meant to part with the draft absolutely and no force or duress was used upon him.

Commendatory Report.—The report by Surgeon General Reypen of the Navy Department, on the work of the naval surgeons, is admirable. It shows the very best of organization, and the most complete and thorough efficiency in this department. Everything was provided for, everything was on time, and never in the history of naval warfare has such care or success been in evidence. The mortality in the hospital ship, itself a new feature, showed no greater percentage than in well-conducted hospitals on shore. The sudden call for hospital accommodations for hundreds of Spanish prisoners was instantly and fully met. An outbreak of yellow fever was localized and stamped out. A daughter of the Secretary of the Navy and other trained nurses volunteered for service and did admirable work. Indeed, the report is one to make us proud that there was one such efficient department in the management of the war.—*The Independent*.

Unavailing Heroism.—A most notable Alpine accident, and one that was marked by as magnificent a display of heroism as can well be described, is that by which Professor Nasse of Berlin lost his life. Dr. Nasse, well-known as the assistant to

Professor von Bergmann, and Dr. Borchardt, with two guides, the four roped together, were crossing the Piz Balne over a snow bridge which was considered quite safe by the guides. The bridge gave way and the leading guide and Professor Nasse fell into the crevasse. Professor Nasse had the rope around his chest and hung in midair for half an hour. To relieve the intolerable strain the leading guide cut the rope between himself and Professor Nasse and disappeared into the depths. The other guide and Dr. Borchardt were then able to pull Professor Nasse up, but he was dead. It is cheering to know that the guide who so willingly offered his own life was not killed, but was found unhurt by a rescue party. But as a heroic action it is beyond all praise. Men have risked their lives on the battle-field in many very noble ways, but there they have the excitement and the lust of fighting to keep them up. Here, however, there was nothing of the kind, almost certain and horrible death stared him in the face. Two actions we can recall which are in some way comparable—the one which happened in England when the driver and fireman of the Great Western express stuck to their engine, so as to stop the train, although being boiled alive, and the other the well-known instance of the steersman of the burning steamer on Lake Erie who stood at the wheel while slowly scorching, so that he might steer the ship to land. The news of Professor Nasse's terrible death was received with the utmost sympathy among medical and lay circles in Berlin, where he had a prominent position as head of the out-patient department of the Royal Surgical Clinic. He had made a good many contributions to modern surgery, and came especially into notice during the late Græco-Turkish war as a leader of the German Red Cross Mission to Constantinople. Professor Nasse resided several months in the Turkish metropolis as chief surgeon to the great military hospital of that city. It was a sad coincidence that on the day of his death the *Official Gazette* published the news of his being decorated by the Sultan in recognition of the services he had rendered to the Turkish wounded soldiers.—*London Lancet*.

Death of a Soldier's Nurse.—Miss R. H. Walworth, a volunteer nurse at the camp at Montauk Point, lost her life from typhoid fever contracted at the camp hospital. She and her mother, Mrs. Ellen H. Walworth, were among the heroic volunteer corps of nurses that early went out from New York City to help the returning sick soldiers. The Walworth family name is one that is historic in the annals of that State, and many and sincere have been the tributes paid to the departed patriotic lady.

The London Hospital.—This institution, said to be the largest hospital in the world, except that at Vienna, is constantly engaged upon improvements. A recent change has been to make a charge of three pence for medicines or for surgical dressings in the out-patient department, it being found that those who can afford this nominal charge give it willingly, the sum being remitted in the case of those really unable to pay it. It is thought that the adoption of this plan will benefit the hospital to the extent of some \$5,000 a year. A feature of the London Hospital is the provision of separate wards for patients of the Jewish persuasion, for whom food is specially prepared in a Jewish kitchen. Four new operating theaters are being constructed, which are to be models of all that modern science can devise, an Australian gentleman having given \$65,000 for this purpose. They will be fitted with an apparatus which will force ice-cooled air into the theaters during the hot weather, and warm filtered air during cold, the pressure being such that under all circumstances there will be a current of air passing from the interior outward. Besides being the largest hospital in the world, after that in Vienna, the London Hospital will, when the present additions and alterations are effected, be the most advanced scientifically.—*American Practitioner and News*, October 1.

Dermatologic Statistics.—In "Impressions and Conclusions Based upon a Study of 5000 Cases of Skin Disease Treated During the Year," Allen (*Med. Record*, October 22) says that "the diseases giving over 1 per cent of the total number and showing the largest number of cases are, in the order of greatest frequency, as follows: Eczema (including all varieties), 985; impetigo contagiosa, 444; pediculosis capillitii, 365; vaccinia, 531; dermatitis 'pediculosa,' 210; urticaria, 170; scabies, 164; dermatitis (traumatica), 142; acne, 141; favus, 139; intertrigo and intertrigal eczema, 127; tinea carinata, 124; tinea tonsurans, 92; tinea furuncle, 97; syphiloderma, 84; dermatitis calorica (including burns), 75; erysipelas, 72; abscess, 70; verruca, 67; pediculosis corporis, 59; pruritus, 58; psoriasis, 58; erythema multiforme, 54.

Osteopathy and the "Medical Age."—In the *Medical Age* of October 25 the following communication from the publisher, Wm. A. Warren concerning the libel suit of William Smith, osteopathist, appeared:

"Dr. William Smith, osteopathist, has a grievance against the *Medical Age*, and demands \$25,000 damages. The ground of his plaint is an editorial, reflecting discredit on Dr. Smith, on the *Journal of Osteopathy*, and on osteopaths in general. The subject is set forth editorially in the *Medical Age* of Sept. 26, 1898, and a reprint of this editorial will be sent on application. I need hardly assure any one familiar with the past record of the *Age*, that William Smith, M.D., D.O., has a large contract on his hands. His quest for damages is likely to prove futile, and his armor will need patching if it is to withstand the hard legal knocks that will be showered and battered upon it before he touches one dollar of the *Age's* money! Pray do not fancy, however, that William Smith and osteopathy are to be lightly dismissed with the contempt that they merit. There is no use in blinking the fact that the lack of efficient organization among reputable medical men has permitted the whole brood of quacks and charlatans to flourish apace. By the strangest irony of fate, Osteopathy, in some respects the most grotesque of medical aberrations, has well illustrated Lecky's dictum that a small but cohesive and determined minority can exert a political influence wholly disproportionate to its real weight and numbers. In Kentucky, thanks to the resolute leadership of a handful of physicians, ably guided by Dr. Mathews, the osteopaths have been driven from the State. Not so, however, in Missouri or—I blush to say it—in Michigan, Vermont, North Dakota, South Dakota, Illinois, Colorado and North Carolina (*American Medico-Surgical Bulletin*). In these more lax and indulgent communities Osteopathy boasts its numerous followers, its "schools of instruction," its periodicals of propaganda, its political influence in legislation, its shameful immunity from the penalties by which society properly seeks to rid itself of quackish parasites. Emboldened by its success, Osteopathy now enters the courts and offers battle to a medical journal which disputes its respectability. The challenge is accepted. In the interest of science, in defiance of a quackery that continues a deep disgrace to an enlightened age and a stain on the communities which give it shelter, the *Age* proposes to maintain its position and to continue its denunciations of the ignorant pretenders who fatten on the sufferings of the credulous and confiding. Having put my hand to the plow in this uncompromising fight with quackery, I beg leave to assure you that there will be no turning back. I need not point out the bearings this contest must have on the interests of legitimate medicine, and I earnestly hope that the *Age* may count on the moral support and commendation of the entire profession."

Premium for a Life-Saving Invention.—The Belgian Government having decided to offer a premium of \$10,000 to the inventor of a paste for matches which will be free from phosphorus, and which will ignite on cloth or on any other surface, a ministerial decree has been issued determining the conditions. The competition will be international in character and will remain open until Jan. 1, 1899.

Telegraphy without Wires.—The compiler of the Consular Reports for September has received from Liège, under date of July 19, a letter from a professor of a San Francisco school of engineering, who has been investigating inventions of wireless telegraphy. The professor refers to the system of Dr. Della Riccia, connected with the Montefiore Institute of Electricity

at Liège. Dr. Riccia has made improvements on apparatus already in use, simplifying it and increasing its power, and claims that he can confine the oscillations of the transmitter to any special point, to the exclusion of all others. In case of communication between war vessels or forts, the message could be transmitted to one alone; in case of fog at sea, the oscillations would not be limited. Dr. Riccia, it is said, can make the presence of a vessel known to another at a distance of thirty miles, and telegraph real messages seven miles.

Explosion of Liquefied Air.—At the Polytechnic Institute of Brooklyn recently a violent explosion resulted from an experiment made by Prof. Irving Fay, with the newly discovered liquid air. It occurred after the class in chemistry had been dismissed, so Professor Fay alone was injured, and it was for a time thought he might lose his eyesight, but this danger has happily been escaped. The agents that were in use, at the time of the accident, were red phosphorus and a waning supply of liquid air, that is believed to have become nearly pure oxygen by the loss of its nitrogen. The exact reaction that took place is not fully understood, but it is probable that the volume of liquid air in the possession of the Professor had been standing exposed to the atmosphere for too long a time to have been a safe exponent of the properties of the new agent. The force of the explosion, like that of dynamite, seems to have been exerted in a downward direction.

No Copper in Green Oysters.—Green oysters have become a subject of fresh discussion. The United States Fish Commission has given renewed attention to the prevalence of green oysters in the Chesapeake region and elsewhere. It is the general opinion among oyster consumers that green oysters are made so by copper, with which they have been contaminated, and that they are therefore unwholesome. But it has been repeatedly demonstrated and announced by the commission that the green oysters owe their color to vegetable matter, which serves as food, and that no impairment of the food value of the oyster results from this condition. The circulation by the press of a report that copper in considerable quantities had been discovered in English oysters induced the commission to make a re-examination of the subject, and this has confirmed previous tests. There is no copper in the green oysters of the United States.—*Sportsman's Magazine*, October.

Gleanings.—Expulsion of a mole containing a four months' fetus.—*Brazil Méd.*, September 1.—Death from anti-diphtheria serum administered for long-continued bronchial asthma in a child of 10 years, with slightly arrhythmic action.—*Semaine Méd.* September 28—Phocas relates two cases of post-operative paralysis after abdominal hysterectomy.—*Journ. de Méd. de Paris*, October 9.—Intraperitoneal injections of oxygen found effective in ascites complicating either tuberculous peritonitis or cirrhosis.—*Klin. Therap. Woch.*, October 16.—E. Fischer keeps a cloth constantly moistened with alcohol over erysipelatous patches and claims that they heal rapidly under it.—*St. Pet. Med. Woch.*, No. 38.—Menelik, King of Abyssinia, has become very much interested in the first hospital established in his capital (erected by the Russian mission), insists upon being summoned to every important operation, and is delighted when allowed to serve as an assistant.—Cyanosis noted as a reliable symptom in the early diagnosis of acute general miliary tuberculosis.—In experiments on eighteen rabbits and guinea-pigs inoculated with various severe infections, it was found that the germ never passed into the milk as long as the teats were intact.—*Gazz. d. Osp.*, October 9.

Societies.

Alabama.—Tri-state Medical Association, Birmingham, October 27.

Connecticut.—New Haven County Medical Society, New Haven, October 27.

Illinois.—Chicago Medical Society, November 2.

Indiana.—Henry County Medical Society, New Castle, October 21; Vanderburgh Medical Society, Evansville, October 18.

Iowa.—Polk County Medical Society, Des Moines, November 1.

Kentucky.—Southern Kentucky Medical Association, Russellville, November 2 and 3; Southwestern Kentucky Medical Association, Mayfield, October 25.

Maryland.—Frederick County Medical Society, Frederick, organized October 30.

Michigan.—Grand Rapids Medical and Surgical Society, October 24; Manistee County Medical Society, Manistee, October 26; Wayne County Medical Society, Detroit, October 20.

Minnesota.—Minnesota Academy of Medicine, Minneapolis, November 2.

Missouri.—Central District Medical Society of Missouri, Sedalia, November 3; Medical Society of City Hospital Alumni, St. Louis, November 3; St. Joseph Medical Society, October 25; St. Louis Medical Society of Missouri, November 5.

New York.—Binghamton Academy of Medicine, October 25; Medical Society of the County of Queens, Jamaica, L. I., October 25; State Medical Association, New York City, October 18, 19 and 20; Suffolk County Medical Society, Patchogue, October 28; Syracuse Academy of Medicine, October 25; Union Medical Society, Hoosick Falls, October 26.

Ohio.—Mansfield Academy of Medicine, October 25; Perry County Medical Society, New Livingston, October 20; Tuscarawas County Medical Society, Canal Dover, October 25.

Pennsylvania.—Bucks County Medical Society, Doylestown, November 2; Pathological Society of Philadelphia, October 27.

Rhode Island.—Medico-Legal Society, Providence, October 27.

Annual Report of Illinois State Board of Health.—This 19 20th annual report contains a valuable summary of the laws and regulations governing the practice of medicine in the States and Territories of the Union including Hawaii. The following is a synopsis:

ALABAMA.—Certificate of successful examination by Board of Censors of the Medical Association of the State or the Boards of Censors of the several county medical societies in affiliation. Diplomas confer no right to practice. Senior Censor, W. H. Sanders, M.D., Mobile.

ALASKA.—No law.

ARIZONA.—Certificate of successful examination by Board of Territorial Medical Examiners, after presentation of diploma from a properly and lawfully organized medical college. Secretary of Board, C. D. Belden, M.D., Phenix.

ARKANSAS.—Practically no law.

CALIFORNIA.—Certificate issued on presentation of diploma from a medical college in good standing issued by one of the State Board of Examiners, regular, homeopathic or eclectic. Secretary representing State Medical Society, G. G. Wadsworth, M.D., San Francisco.

COLORADO.—Certificate based on diploma from a recognized medical college or successful examination by State Board of Medical Examiners. Secretary of Board, T. A. Hughes, M.D., Denver.

CONNECTICUT.—Certificate of successful examination by committee appointed by State Board of Health. Regular, homeopathic or eclectic. Diplomas confer no right to practice. Secretary representing State Medical Society, G. A. Lindsley, M.D., New Haven.

DELAWARE.—Certificates conferred only by Medical Council after presentation of diploma from a legally incorporated medical college and successful examination by Board of Medical Examiners, either regular, homeopathic or eclectic. Diplomas confer no right to practice. Secretary of Medical Council, I. S. Vallendigham, Middletown.

DISTRICT OF COLUMBIA.—License by Board of Medical Supervisors after successful examination and diploma from a legally authorized medical college. Secretary of Board, W. G. Woodward, M.D., Washington.

FLORIDA.—Certificate of successful examination by District Board of Medical Examiners. Diplomas confer no right to

practice. Secretaries of District Boards (from Polk's Medical Directory, 1898), 1st, C. B. McKinnon, M.D., Pensacola; 2d, G. W. Lamar, M.D., Quincy; 3d, W. R. Chalkee, M.D., Lake City; 4th, R. H. Dean, M.D., Jacksonville; 5th, G. E. Welch, M.D., Palatka; 6th, L. W. Weedon, M.D., Tampa; 7th, R. L. Harris, M.D., Orlando.

GEORGIA.—License issued after satisfactory examination by the Board representing the regular, homeopathic or eclectic schools of medicine. Secretary representing regular school, E. R. Anthony, M.D., Griffin.

HAWAII.—Under the laws of the Republic of Hawaii certificates are issued to graduates from recognized colleges after a satisfactory examination by the Board of Health.

IDAHO.—Certificate from State Board of Medical Examiners based on diploma and satisfactory examination by the Board. Secretary, C. L. Sweet, M.D., Boise.

ILLINOIS (law now in force).—Certificate by the State Board of Health based on diploma from a recognized medical college or a satisfactory examination by the Board. (Proposed law).—License by Board of Medical Examiners based upon diploma of a recognized medical college and a satisfactory examination by the Board. License to be renewed annually, at the discretion of the Board. Secretary, J. A. Egan, M.D., Springfield.

INDIANA.—Certificate based upon a diploma from a recognized medical college or after a satisfactory examination by the State Board of Medical Examiners. Secretary, W. F. Curryer, M.D., Indianapolis.

INDIAN TERRITORY.—Cherokee Nation: An examination by Board of Medical Examiners. Secretary, I. W. McClendon, M.D., Colgate. Choctaw Nation: the same, except an annual fee of \$10 for a permit.

IOWA (In force Jan. 1, 1899).—Certificate from State Board of Medical Examiners based upon a diploma from a recognized medical college and satisfactory examination by the Board. Secretary, J. F. Kennedy, M.D., Des Moines.

KANSAS.—Registry of diploma from some "respectable medical college," or certificate of qualification from some state or county medical society. Secretary of State Board, H. Z. Gill, M.D., Pittsburg.

KENTUCKY.—Certificate from State Board of Health based upon diploma from "some reputable and legally chartered medical college endorsed as such by the Board." Secretary, J. N. McCormack, M.D., Bowling Green.

LOUISIANA.—Certificate based upon diploma from a medical college in good standing and a satisfactory examination by the State Board of Medical Examiners. Secretary, representing State Medical Society, H. S. Cocram, M.D.

MAINE.—Certificate of successful examination by the State Board of Registration. Secretary, A. K. P. Meeerve, M.D., Portland.

MARYLAND.—A certificate based upon a satisfactory examination by the State Board of Medical Examiners. Secretary, representing Medical and Chirurgical Society of Maryland, J. McP. Scott, Hagerstown.

MASSACHUSETTS.—License after a satisfactory examination by the State Board of Registration in Medicine. Secretary of Board, Edwin C. Harvey, Boston.

MICHIGAN.—Registration with the county clerk of a diploma from any legally authorized medical college.

MINNESOTA (In force Jan. 1, 1899).—License issued by the State Board of Medical Examiners after a satisfactory examination and presentation of evidence of having attended four full courses, at a recognized medical college, of at least twenty-six weeks each, no two courses being in the same year. Secretary, J. B. Brimhall, M.D., St. Paul.

MISSOURI.—Similar to Illinois. Secretary of State Board of Health, Paul Paquin, M.D., St. Louis.

MONTANA.—A certificate based upon a diploma from a recognized medical college or after a satisfactory examination by

the State Board of Medical Examiners, and evidence of having attended four courses of lectures of at least six months each. Secretary, Henry Chapple, M.D., Billings.

NEBRASKA.—A certificate issued by the State Board of Health upon a diploma from a "legally chartered medical school or college in good standing." Holders of diplomas must have attended four courses of lectures in four separate years. Secretary of Board, B. F. Crummer, M.D., Omaha.

NEVADA.—A record of diploma filed with county recorder from "some regularly chartered medical school."

NEW HAMPSHIRE.—License by State Board of Medical Examiners after a satisfactory examination by the Board, or based upon license from another State having an equal standard of qualifications. Secretary representing New Hampshire Medical Society, J. T. Greely, M.D., Nashua.

NEW JERSEY.—A license after successful examination by the State Board of Medical Examiners, diploma from a recognized medical college. Candidates must have studied medicine four years, including three courses of lectures in different years, and present evidence of preliminary education. Secretary of the Board, E. L. B. Godfrey, Camden.

NEW MEXICO.—Certificate based upon a diploma from a medical college in good standing, or a satisfactory examination by the Territorial Board of Health. Secretary, J. M. Cunningham, M.D., Las Vegas.

NEW YORK.—License issued by State Board of Examiners, after a satisfactory examination and evidence of having studied medicine not less than four years in a medical college having a satisfactory standard. Secretary representing New York State Medical Society, Melvil Dewy, M.D., Albany.

NORTH CAROLINA.—A license issued upon successful examination by the State Board of Medical Examiners. Diploma confers no right to practice. Secretary, H. B. Weaver, M.D., Asheville.

NORTH DAKOTA.—Similar to North Carolina. Secretary, H. M. Wheeler, M.D., Grand Forks.

OHIO.—(In force Jan. 1, 1899).—Certificate issued by a State Board of Registration and Examination, based upon diploma from a college requiring four years of study and in good standing with the Board. Secretary of the Board, Frank Winders, M.D., Columbus.

OKLAHOMA.—A license based upon a diploma of a "medical college," or after a satisfactory examination by the Board of Examiners. Secretary, L. Haynes Buxton, M.D.

OREGON.—A license issued by the State Board of Medical Examiners after a satisfactory examination. Secretary, B. E. Miller, M.D., Portland.

PENNSYLVANIA.—A license granted by the Medical Council after a satisfactory examination and a diploma from a recognized medical college. Secretary, Hon. J. W. Latta, Philadelphia.

PORTO RICO.—Graduates from a reputable medical college will probably be allowed to practice.

RHODE ISLAND.—A certificate based upon a diploma from a recognized medical college having a four-year course, or after a satisfactory examination by the State Board of Health, Secretary, G. T. Swarts, M.D., Providence.

SOUTH CAROLINA.—A certificate issued by the State Board of Medical Examiners to holders of diplomas after a successful examination. Secretary, S. C. Baker, M.D., Sumter.

SOUTH DAKOTA.—A license by the State Board of Health based upon a diploma from a recognized medical college. Secretary, F. H. Files, Sioux Falls.

TENNESSEE.—A license after a satisfactory examination by the State Board of Medical Examiners. Secretary, T. J. Hapel, Trenton.

TEXAS.—A license after examination by the District Board of Medical Examiners.

UTAH.—A certificate issued to holders of diplomas after an

examination by the State Board of Medical Examiners. Secretary, B. Stringham, M.D., Salt Lake City.

VERMONT.—A license based upon a diploma from a reputable medical college, or after examination by the Board of Censors. Secretary, representing Vermont Medical Society, H. H. Lee, M.D., Wells River.

VIRGINIA.—A license after an examination by the State Board of Medical Examiners. Secretary, R. S. Martin, Stuart.

WASHINGTON.—Similar to Virginia. Secretary, J. H. Hoxley, M.D., Spangle.

WEST VIRGINIA.—A license after an examination by the State Board of Health. Secretary, A. R. Barbee, M.D., Mount Pleasant.

WISCONSIN.—A license based upon a diploma from a recognized medical college, or after a satisfactory examination by the Board of Medical Examiners. Secretary, H. M. Ludwig, M.D., Richland Center.

WYOMING.—The record of diploma with the Registrar of Deeds.

Philadelphia.

PREVENTION OF DIPHTHERIA.—For several weeks there has been a gradual increase in the number of cases of diphtheria among children, especially those attending the public schools of the city and it became so general that it at once attracted the attention of the Board of Health, which body is making heroic efforts to reduce the number of cases, on the principle that "an ounce of prevention is worth a pound of cure," and orders have been issued giving definite information to janitors of the different buildings used for school purposes describing in detail the proper means of using disinfectants about the rooms, halls and stairways. Dr. Woodward of the Board of Health has presented a resolution that the diphtheria placard should not be removed from any house in which there has been a case of diphtheria and that there shall be no disinfection of bedding or clothing until bacteriologic examination made in the laboratory of the Board of Health shall have demonstrated that the bacilli of diphtheria are absent from the throat of the patient.

RED CROSS SOCIETY.—The building formerly owned by the Pennsylvania Epileptic Hospital has been turned over to the Red Cross Society of Pennsylvania for the establishment of a new hospital. The building has been furnished by the equipment formerly used at Camp Meade, but owing to the work having been finished at that place the material was brought here. A staff of five physicians will look after patients, and is composed of Drs. Richard Clemon, Samuel Ashhurst, Clarence B. Franklin, Samuel Gerhardt and I. W. O'Neil. Twenty nurses will be in attendance. The capacity of the hospital is sixty beds placed in two wards, and it is stated that the Red Cross Society takes great pride in its new venture and is leaving no stone unturned to make it a first-class hospital. A train was dispatched during the week to Camp Meade and sixty soldiers taken to the new hospital. The institution is in need of supplies such as linen, tables, chairs, china, tinware, etc., which it is hoped will soon be replaced by new material.

HOSPITAL TRAINS.—The War Department has requested the National Relief Association to send hospital trains to Camp Meade and bring ninety sick soldiers to Philadelphia hospitals. October 30, twenty-four patients were brought here and sent to the Presbyterian and Jefferson Hospitals. October 31, another train was dispatched under the charge of a staff composed of ten physicians from the University, Presbyterian and German Hospitals, together with a corps of twelve nurses. November 1, at the request of the War Department, the National Relief Association dispatched another train to Camp Meade returning with fifty six patients, many of whom are suffering from typhoid fever. Of this number twenty were sent to the St. Joseph Hospital, twenty to the German Hospital, and sixteen to the Jewish Hospital. On November 4, it was proposed to bring about 150 soldiers to be assigned to the different hospitals.

MORTALITY STATISTICS.—For the week ending November 12, there was a total of 394 deaths, an increase of 46 over last week and of 61 over the corresponding period of last year. Of the total number of deaths, 82 occurred in children under the age of five years.

KNOCK-OUT DROPS GIVEN SOLDIERS.—Two soldiers, members of the Fourteenth Pennsylvania Volunteers, while in attendance upon the jubilee festivities here last week became acquainted with a man who gave them liquor from a bottle he took from his pocket. Shortly afterward they were found in an unconscious condition and were taken to the hospital. The death of one man had recently occurred under similar circumstances. An autopsy was made by the Coroner's physician, but the actual cause of death has not been divulged, though it is reported that the patient died of poison. Detectives are at work upon all the cases and it is thought traces have been found which may lead to the apprehension of the guilty persons. While chloral is the usual ingredient of knock-out drops, it is not yet known whether or not it is responsible for the serious illness of these two soldiers and the death of the one man.

CAMDEN.—Several members of the Water Committee of the city of Camden recently discussed the question of better water for that city. From the fact that the contractor had cut off the supply from the artesian wells and had started to draw the city's supply of water from the Delaware River, it is feared that an epidemic of typhoid fever will sweep over the town. It is stated that the reports from the Board of Health go to show that since the artesian system had been in vogue typhoid fever had diminished from 40 to 60 per cent., which decrease was thought to be due to the purer water. The trouble came about over the fact that the city demanded of the contractor that a test be made regarding the amount of water supplied, but this was refused and the supply of water cut off. In this connection it may be stated that the trial of Peter E. Smith of Philadelphia, who is charged by Walter N. Stevenson a member of the City Council, with an attempt to bribe the latter, has been before the court this week. Strange to say Smith is also a member of the City Council. Stevenson stated under oath that Smith offered him \$5000 for his vote in favor of the Schuylkill Valley Water Bill, which attracted so much attention during the epidemic of typhoid fever here last spring. On the other hand, the defendant has introduced a plea of alibi, and witnesses have sworn that it was impossible for him to have been present in Stevenson's office at the time the latter states the bribe was offered. Charges and counter-charges are being made by both parties, and the case elicits no little public interest. But the fact is painfully evident, at any rate, that the people are still using unfiltered Schuylkill water, as proved each week by the number of deaths from typhoid fever.

UNIVERSITY OF PENNSYLVANIA.—Owing to the death of Dr. William Pepper, president of the alumni of the University of Pennsylvania, the Board of Managers of the General Memorial Society recently elected Effingham P. Norris, '71, to fill the vacancy. A memorial gate will be erected on the University campus, by the class of 1872, to cost \$3000. The General Alumni have undertaken to raise the balance of \$200 solicited by the Houston Club Memorial Committee for the erection of an archway in the new dormitory system in memory of the students who were killed during the late Spanish war.

GIFT OF \$1,000,000.—Mrs. Imogene Bennett Wellens, daughter of Joseph M. Bennett, has begun the contest against the probate of the will of the deceased. It will be remembered that Joseph M. Bennett recently gave to the University of Pennsylvania certain pieces of property adjacent to the University grounds, upon which were to be erected certain buildings to "further aid and encourage the said trustees in carrying out more practically and thoroughly the co-education of women and girls." . . . Besides this bequest various other ones were made to charitable institutions. In the will Mrs. Wellens was entirely ignored.

PRECAUTIONS AGAINST THE PLAGUE.—Owing to the receipt of a message by the Marine-Hospital Service and by public reports of the death of three persons from bubonic plague in Vienna, the quarantine officers of this city have received instructions from Washington to use stringent measures in regard to preventing the introduction of the disease by steerage passengers who have been through the infected district of Europe.

REPORT OF NATIONAL RELIEF COMMISSION.—Mr. George C. Thomas, treasurer of the National Relief Commission, makes known the following contributions: Cash previously received, \$78,173.47; items, \$85; value of supplies received to date, \$40,345; grand total, cash and supplies, \$118,603.47.

NATIONAL RELIEF ASSOCIATION.—At a recent meeting of the executive committee of the National Relief Association, two gentlemen were appointed to go to Washington to confer with the Secretary of War relative to the future work of the Commission. The committee is composed of President Converse and Secretary French. It will be remembered that the National Relief Association has been doing noble work in caring for the sick soldiers in the army camps and in bringing them to this city to be placed in well-equipped hospitals. It now seems that the Commission is being overwhelmed and it is stated that much of the work now done by them in fact should be done by the government. It is also reported that the Commission has been bearing part of the government's expense in this matter and the two members have been dispatched to Washington to look after the matter.

HONOR TO NAME OF FORMER PHILADELPHIAN.—The President has given direction to the proper authorities in charge designating that the general field hospital at Camp Lexington, Ky., be named John Blair Gibbs, U. S. A., General Hospital, in honor of that much beloved officer who was killed in the second skirmish of the American troops at Guantanamo on the night of June 12. Dr. Gibbs formerly lived in Philadelphia, graduating at the University of Pennsylvania, but in recent years lived in New York, where he held prominent positions on the staff of the Roosevelt Hospital and a prominent medical college.

Washington.

HEALTH OF THE DISTRICT.—The report of Health Officer Woodward for the week ended October 29 gives the total number of deaths as 120—65 white and 55 colored. The principal causes were: Apoplexy, 8; consumption, 12; diphtheria, 7; heart disease, 13; diseases of kidneys, 8; malarial fever, 5; pneumonia, 10; scarlet fever, 1; typhoid fever, 6. The total number of births was 105—53 white and 52 colored. At the close of the week there were 139 cases of diphtheria and 106 cases of scarlet fever under treatment.

HEALTH REGULATION ENFORCED.—The father of a child convalescing with scarlet fever was fined in the police court for violating the law for the prevention of the spreading of contagious diseases. One of the medical inspectors of the health department found the convalescing child on the street before the official quarantine had been removed; the father was held responsible and was fined \$15.

PHYSICIANS APPOINTED.—On the recommendation of Health Officer Woodward, John H. Stoutenburgh has been appointed by the Commissioners to the position of Assistant Medical Sanitary Inspector, with a compensation of \$2.50 *per diem*. J. F. Reppeti will act as physician to the poor during the assignment of Dr. Stoutenburgh. L. E. LeFetra has been appointed medical school inspector in New York City. Dr. LeFetra passed first in the competitive examination for the position, 276 applicants being examined.

SURGEON SUEB.—A patient entered suit recently against Dr. George C. Burton to recover alleged damages in the sum of \$25,000. The plaintiff claims to have suffered from a shortening of a limb after a fracture, and sets up the stereotyped charge of "unskillful doctor."

PUBLIC HEALTH COMMITTEE.—At the meeting of the Committee on Public Health of the Washington Board of Trade, recently held, it was decided to recommend to Congress the filtration of the city water-supply, the extension of the sewer system, and the reclamation of the Anacostia flats. The latter recommendation was considered particularly important, as a large number of the paludal diseases prevalent in Washington are traced directly as originating from these flats. The report of the Commandant of the U. S. Navy Yard, the surgeon-in-charge of the Government Hospital for the Insane, and the Washington Asylum Hospital, point out the disease-spreading influence of this cess-pool. The Superintendent of Public Schools for the eastern section of the city, submitted a tabulated statement showing the number of cases of malarial diseases among pupils who reside in this locality.

THE FORTNIGHTLY CLUB.—The 79th meeting of the Fortnightly Club was held at the residence of Dr. A. F. A. King, on the 28th ult.

Work of Fiction.—Dr. Weir Mitchell's novel, "The Adventures of Francois," has been issued simultaneously in New York, London, Canada and Australia. In New York the twenty-fifth thousand was on the press before publication.

An Effect of Diet.—Mrs. Dix: "Don't you think your husband is rather headstrong for an invalid?" Mrs. Hix: "Yes, and the doctor's to blame for it, too." Mrs. Dix: "Indeed! And why, pray?" Mrs. Hix: "He refuses to allow him to take any nourishment but goat's milk."—*Chicago News*. But suppose the patient should become bull-headed in his obstinacy?

CHANGE OF ADDRESS.

Allen, C. J., from East Barnard, Vt., to 6 Winthrop St., Winchester, Mass.
Christenson, A., from Washburn to Wausau, Wis.

ADDRESS.

MEMORIAL ADDRESS ON THE DEATH OF DR. I. N. QUIMBY,

CHAIRMAN OF THE SECTION ON STATE MEDICINE,

BY CHAS. H. SHEPARD, M.D.

CHAIRMAN PRO TEM.
BROOKLYN, N. Y.

The loss of our Chairman, Dr. Isaac N. Quimby of New Jersey at a time when we were expecting so much from him, is a heavy blow.

Dr. Quimby was one who impressed all favorably at first sight, but a closer acquaintance more distinctly revealed his noble qualities. His genial manner and forcible way of presenting whatever he had to say, whether in public debate or in the private circle, won for him a host of friends.

ISAAC N. QUIMBY, M.D.

Born Aug. 5, 1831, and educated in New Jersey, he early turned his attention to the medical field of his native State, graduating in 1859, from the University College of New York, the second in his class, with a special certificate of honor. Upon the breaking out of the Rebellion Dr. Quimby entered the army as a volunteer surgeon, serving with Gen. McClellan's forces in the Chickahominy swamps. He was at Harrison's Landing, and at Antietam, remaining with his division until after the battles of the Wilderness, when on account of illness he returned home, and shortly after resumed his medical practice.

His experience eminently qualified him to fill a lectureship in the spring course of the University Medical College in 1866-68, and also as assistant to

Prof. A. C. Post, in his surgical clinic. Soon after, his activity found vent in the establishment of the Hudson County, now Christ's, Hospital, of which he was the originator in 1868, and he continued as its surgeon until 1873, at the same time being one of the attending surgeons of the City Hospital, Jersey City.

His membership in the AMERICAN MEDICAL ASSOCIATION, and as one of the Judicial Council, was marked by a broad and liberal spirit that gave him a large popularity, and nearly landed him in the presidential chair. His visits abroad as a delegate from the AMERICAN MEDICAL ASSOCIATION, to the International Medical Congress in London, in 1881, again to Copenhagen, in 1884, and at Rome, Italy, in 1894, added to his ripe experience and gave him a large fund of knowledge which made him more useful for the remainder of his days. This same spirit drew him into the membership of the numerous medical societies, including the American Medical Temperance Association, of which he was one of the founders, and its vice president until his death.

His labors in the temperance field were marked by a thorough earnestness. He approached the subject from a scientific standpoint, his experience both in hospitals and private practice confirming him in the conviction that total abstinence from alcohol was the only safeguard for our people. No one was more ready to make sacrifices, either of time or money, for this great truth. With both pen and voice he sought unweariedly to promote this movement, which seemed so important to him.

But of all the causes he espoused, that of scientific temperance education in the public schools throughout our land appealed to him most forcibly as the one foundation of all reforms, in that it commenced at the fountain source. His clear mind appreciated the advantage to humanity which would be gained by having our children taught the facts with regard to the action of alcohol and other narcotics. For five years he was senior member of the medical committee having in charge that noble work of enlightenment, and in no place will he be more missed than in that advisory board. His earnestness, combined with quick perception and fearless action, kept him always in a leading position.

The practical side of Dr. Quimby was shown by the fact that he devised several important improvements in surgical operations, and a number of valuable papers illustrating them are on record. Not alone to the medical field was his work confined, but his public spirit gave him the high honor of being president of the first Citizen's Association of Jersey City, in 1870, which was instrumental in breaking the corrupt official ring which then controlled the affairs of that city. Again, his industry and zeal for the good of his fellow-citizens was marked in exposing and blocking corruption in the State legislature in

1882, and his integrity of character was such as to bring to him the nomination, in 1883, of Governor of New Jersey, by the prohibitionists, which honor he declined.

In the midst of his busy life this great man has fallen, and all of us feel that we have lost a genial friend and a trusted counsellor, who was ever ready to give us of the best that he had. Taken ill on the 29th of April last, his life forces were so exhausted that he could not rally, and in one week he passed to the great beyond. On May 11 he was laid in his final resting-place, leaving his bright example as a valuable heritage to cheer us on in every good word and work.

What lesson has his life left for us? He was sixty-seven years young, for he could not be called an old man. One thing it may teach us: not to be so prodigal of our life forces. It is likely that had he been a little more conservative of his strength he might still have been with us. Let us then study more earnestly those things that tend to the preservation of life and the prevention of disease, which our Section so nobly represents. Preventive medicine, as we understand it, leads to the prevention of the use of medicine by advancing along sanitary lines, with such care of the body and its environments that disease will be prevented, and the use of medicine rendered unnecessary.

This work is committed to our hands, and let us realize that it is not for today alone that we plod, but as the movement passes along to succeeding generations it will gather increasing force and become a blessing to millions yet unborn. Thus shall we aid in the great work of humanity.

By all means let us have a Department of Health.

ABOULIA IN RELATION TO HYSTERIA.

Presented to the Section on Neurology and Medical Jurisprudence, at the Forty-ninth Annual Meeting of the American Medical Association, held at Denver, Colo., July 7-10, 1898.

BY L. HARRISON METTLER, A.M., M.D.

Professor of Physiology of the Nervous System in the College of Physicians and Surgeons of Chicago (Medical Department of the University of Illinois).

CHICAGO.

That hysteria is a cerebro-spinal neurosis is now an accepted fact. In its many neuromimetic manifestations it presents both a psychic and a purely neurotic front. It is a mental trouble, but has associated with it at times undoubted sensory-motor disturbances. Sir James Paget used to say that the hysteric exclaims, "I can not;" that it looks much as if it were "I will not;" but that in reality it is, "I can not will." This is one of those clever generalizations that cover much knowledge, but still leave much unsaid. Certain paralyzes and anesthetics of hysteria can not well be attributed to volitional influences, at least in their late manifestations. Something more than a mere oblivion of the will power must be invoked to account for some of the singular phenomena revealed in connection with the special senses. Many of the visceral and vasomotor symptoms are clearly beyond the power of the patient's volitional faculty. Hence, hysteria must be recognized as a double-faced phenomenon. There is a clearly-defined affection of certain centers lower than those that subserve the purposes of mentalization. Hysteria is not entirely an

affair of the brain and the will. This fact has introduced much confusion into the study of the pathology of the disease. Can it be possible, in view of this double-sidedness of the symptoms of hysteria, that the latter is really a combination of two affections: a mental (psychic, volitional) and a more strictly neurotic (subpsychic, ganglionic)? Some have so thought, but the distinction is arbitrary, for mentalization is as much neurotic as is any more strictly sensory-motor manifestation.

Without doubt, hysteria is *ab origine* a functional disturbance of that part of the encephalon or cerebral center concerned in the make-up of the so-called faculty of the will. On the other hand, it is equally true that many of the symptoms of hysteria, such as hemianesthesia and anuria, reveal a functional disturbance of nerve centers much lower than those of the cerebral cortex. Therefore, either we have two forms of disease under the head "hysteria"—a cerebral and a spinal neurosis—or we have a general concomitant neurosis of the whole cerebro-spinal apparatus, its manifestations revealing a variety in harmony with the various functional characteristics of the different centers involved; or we have a single disease, a functional disturbance of the cerebral (psychic) centers involved in the constitution of the intellectual faculties (especially the so-called volition) and this in turn affects secondarily the lower or subcerebral centers. The first two views are not as popular as the last. Gowers seems to accept the third view, for he says "it is certain that the disease (hysteria) can only be really cured by the restoration of the normal balance of cerebral function but the secondary disturbance of lower centers (e. g., vasomotor) may at times preponderate over that which can be recognized in the highest, and may be independent in their degree and in some cases apparently (though not really) in their occurrence." My own observations, both here and in Paris, incline me strongly to regard hysteria as primarily a cerebral trouble, an aboulia, and it seems to me that the aphorism of Sir James Paget is in the main correct.

Now, to harmonize this theory of hysteria with the manifestations of the disease in the lower or subpsychic centers, I have for some time past felt that there must be a change made in some of our notions in regard to the so-called volitional faculty. For example, it seems clear enough to me that every case of genuine hysteria (in which category I do not class hysterical manifestations of purely reflex origin) has its start in a disturbance of the will power, but if I regarded the will as a distinct entity, a special faculty with a special habitat, I do not understand how it can *directly* affect the lower, involuntary centers. I can not comprehend how an individual's disturbed will power can bring about a hemianesthesia and its transference. I must reconstruct my old psychologic ideas in regard to the will, or else relinquish the view entirely that the will is at all concerned in the phenomena of hysteria. I can not do the latter, and so I have accepted a theory of the will which seems to me logical, and on the basis of which I see my way clear to an explanation of the phenomena of hysteria.

What is the will and where is it located? Is it, as some of the older psychologists taught, an intellectual faculty, existing *per se* and having a local habitat in the brain? The will-function has obviously to do with every voluntary organ and tissue in the body, and if it were possible to definitely locate its center, say

somewhere in the fore-brain, much of the confusion now surrounding pathology would vanish. It would then be comparatively easy to understand how this faculty, seated in diseased brain tissue, might emit or receive abnormal impulses from all the organs of the body. Such an explanation would be eminently physical and easy of elaboration. Such an explanation would rest, however, upon an erroneous conception of the prime nature of volition. *The will is not a faculty that emits or receives anything. It is a term, a definition, merely expressive of a choice, the preponderance of a motive, the outward representation of an inward impulse that is stronger than the other impulses.* The manifestation of volition usually terminates in an action, but this action is not the result of the operation of some particular volitional center in the cortex; it is the result of certain ideas or feelings (impulses) which preponderate at the time and so involve more or less the whole sensory-motor apparatus. In the language of Ribot, "voluntary activity appears to us as a stage in that progressive evolution which proceeds from simple reflex action, where the tendency to movement is irresistible, to the abstract idea, where the tendency to action is at the minimum." The will is thus merely a consciousness of a kind of internal, mental reflex. Mind is made up of sensory-motor activities, real or representative. On the one hand, a vast quantity of afferent impulses, pouring in through the various avenues of special sense and being stored up in the brain by means of heredity in the race and simple memory in the individual, interweave themselves into latent ideas and feelings. These latent impulses, awakened into activity by newer incoming impulses, set into play the motor or idio-motor representative centers, which send out efferent impulses to terminate in muscular action. The transitional process that takes place within the brain from afferent to efferent impulse is recognized in consciousness, and is spoken of as the exercise of the will. As I have just intimated, the time of the reception of the afferent impulses that ultimately go to make up the mental world of ideas and feelings and the time when the corresponding efferent impulses that terminate in voluntary action are sent out need not necessarily be the same or even successive. If a voluntary act is performed today (efferent impulse), the preponderating idea or feeling which gives it birth (afferent impulse) may have been acquired years before and have lain dormant in the meanwhile. The essential fact in regard to voluntary action is that it is always necessarily preceded by some idea or motive, and this idea or motive may have been stored up by memory or by heredity years before. The reflex character of the will is the point to be insisted upon. It is made up always of an antecedent and a consequent; the transference of the former into the latter is what consciousness recognizes and denominates the will.

Upon first thought, this reflex theory of the will would seem to banish all notion of its freedom, but here again the error is made that the will is a special faculty, a thing by itself, of which freedom may be predicated. But there is no such entity as the will, and a thing that does not exist can not be said to be bounden or free. The so-called will, let it be repeated, is merely the expression or conscious representation of a set of impulses acting more vigorously at the moment than any other set of impulses. The phenomenon of inhibition illustrates well this conception of the will. Take for example the depressive

effect of fear. A child learns by observation when its guardians are angry with it. It sees the raised hand and the frown on the face. It learns to associate these signs with punishment and pain (afferent impulses). The memory of pain (latent impulse) awakens a mental state in which certain intended actions are inhibited (efferent impulse). At times these awakened memories (latent impulses) of pain are overridden by others (also latent impulses) more powerful, such for instance as some strong feeling of pleasure expected of the intended action, and as a result the desired inhibition does not obtain. In the latter case the child does what it wanted to in spite of the threatened punishment. The afferent impulse which awakened in memory the idea of pleasure in connection with the intended action was stronger than the afferent impulse which was associated in memory with the idea of pain. Hence the efferent impulse represented by the child doing what it intended to do was different. It looks as though the child willed differently; in reality there was merely a conscious transference from one action to another in accordance with the relative strength of the preceding motives (afferent impulses).

A burglar fears the law to a certain extent and his memory of punishment, acquired by instruction or by actual experience, inhibits him so much in his acts that what he does he does by stealth and under the cover of darkness. If the motive for burglarizing be much stronger than his fear of punishment he will be less restrained and bolder. His mental inhibition will be overcome by his mental avariciousness. This mental conflict, this internal struggle between motives of various strengths, these motives having all been acquired some time previously through the special senses, terminates in some corresponding form of action, and to the onlooker from the outside it appears as though the man had merely exercised some faculty, the will, in deciding to act as he did. Two latent impulses may at times neutralize each other and we say of them, the individual will is paralyzed. A burst of anger, for instance, may be made to suddenly vanish by a recollection of a terrible accident to the victim of the anger.

In all these instances the actions of the individual are "willed" in accordance with the predominance of this or that motive; but the "willing" process is not the result of an action on the part of some special faculty seated somewhere in the frontal lobe and directing this muscle or that organ to functionate. The will is, therefore, psychologically at least, "an individual reaction," and "that which is inmost to us."

"The ego, albeit an effect, is a cause and that in the strictest sense." "To sum up, we have seen that from the lowest reflex action to the highest act of will, the transition is imperceptible and that we can not say precisely where volition proper, that is the personal reaction, begins. The difference is the most pronounced at the two ends of the series: at one end extreme simplicity, at the other extreme complexity; on one hand a reaction that is ever the same in all the individuals of the same species, on the other a reaction which varies according to the individual. Simplicity and permanence, complexity and change are here paired" (Ribot). In the consideration of hysteria and its management this conception of the will is of immense importance and throws light upon much that has heretofore been dark.

This conception of the will involves the idea of a

reflex, or as Ribot expresses it, a reaction. Aboulia means, therefore, a paralysis of the psychic or mental reflex. According to the latest physiologic data, the cortex is as much peripheral in relation to the centers of subconsciousness as are the integument, muscles, etc. An impulse originating in the cortical motor area is *reflected* through the lower subcortical ganglia and anterior cornua to its appropriate muscle just as much as though it had been reflected from some point in the skin around through the anterior cornua to the corresponding muscle. We are all familiar with the reflex picture presented when some portion of the body comes unexpectedly in contact with a hot iron. The reflex picture produced by an awakened sensory area of the cortex is just the same, though not as apparent as the former. Let me illustrate: Suppose I move my arm. The older psychology would say that such a movement being voluntary, originated in some special volitional faculty. Upon a moment's reflection I think it will be seen that such a movement of the arm, though originating in the cerebral cortex, is as much of a reflex as if the same movement had been produced by touching a hot piece of iron. The only difference is, that consciousness is *immediately* cognizant of the former reflex. When I "willed" to move my arm, I did so from some motive, else there would have been no movement. Inertia is as much a law of the mental as of the physical world. In analyzing the motive that caused me to move my arm, there is found underlying it some previous sensory or apparent impulse which may have immediately preceded the movement or have been stored up in memory a long time before. Some discussion I may have had with a friend about the movement of my arm, or some desire I may have had to show my prowess, which desire may have been originally implanted in me by some one praising or criticising me; or any one of a thousand different reasons may have led me to move my arm. I certainly had a motive for moving it at all, and that motive was created out of some influence from the outer world exerted upon me through one or more of my special senses at or prior to the moment when the arm was moved.

Suppose I touch a hot iron and then in spite of the pain, keep my hand on the iron. Is not that a pure voluntary act in direct opposition to a reflex? No; in such a case the cortical reflex is merely stronger than the cutaneous. Why do I keep my hand on the heated iron in spite of the pain? Simply because I have a motive for so doing. That motive may be the love of praise, emulation or experimentation, but whatever it is, it is based upon some previous sensory impulse poured in upon me from the outer world. Those impulses have been received, and if they have been latent, have been stored up in the sensory cortex. The matter may be formulated somewhat thus: No motive, no voluntary act; no sensations, no motive; hence all voluntary acts are in their last analysis referable to prior sensations and the so-called will is thus shown to be a sensory-motor reflex.

I grant this does not leave much room for the idea of a "free will," but it appears to me as a most rational explanation of volition, which in its final analysis proves to be merely the personal reaction of the individual to past and present impulses. The "wills" of different individuals, or their personal reactions differ just as the sensibilities of all mere protoplasm, the amebæ, for instance, differ in their response to exter-

nal irritation. If this explanation of "will" be well understood, much can be made clear as to the nature and treatment of hysteria.

We call hysteria a neurosis, a neuromimesis. In its typical form it seems to be a rational disorder, almost an aboulomania; yet there are symptoms, as I have said before, that seem to lie outside of the influence of the will. It is both a psychic and purely neurotic disease. Psychosis and neurosis are, however, the same. Mind is made up of sensory-motor phenomena or their cortical representation. I have endeavored to show that "will" especially is merely a sensory-motor reflex, and, therefore, hysteria from every point of view is simply a neurosis. It is a neurosis of the cerebro-spinal system involving its great sensory-motor reflex function. In idiopathic hysteria it is the higher arc, the cortical reflex arc, that seems to be affected; in hysterical manifestations due to extra-neurotic lesions it is the lower or subcortical reflex arc that is involved. The reflex character of the hysterical manifestations caused by a diseased ovary are obvious enough at times, but while not so obvious, nevertheless just as much of a reflex is the hysteria produced by cortical trouble such as may have been produced by bad heredity, bad education, bad discipline and other factors that enter into the making of the individual's character, *his personal reaction*. We say a hysterical patient's will-power is at fault; as a fact, however, her higher sensory-motor reflex apparatus is at fault, and she does things and reveals symptoms because certain bizarre impulses have taken the place of more rational and appropriate impulses. The trouble may be entirely on the sensory side of the arc, and in most cases it is; then, in conjunction with the various anesthetics, there may be complete absence of choice between motives or complete non-volition (aboulia). Again, the impulse from the sensory side of the arc may be so feeble as to awaken only the feeblest sort of a motor response (partial aboulia). Thirdly, the impulse from the sensory side may be so abnormal and extraordinary as to terminate in the strangest sort of movements (aboulomania). A hysterical patient, therefore, may exhibit sensory or motor paralysis (volitional) from mere absence of appropriate sensory impulses, or from two or more sensory impulses conflicting and neutralizing one another; or, she may reveal the strangest sort of motor symptoms and assume attitudes (for sympathy and effect, we say) because her motives (sensory impulses), past and present, have been unnatural and inappropriate. Illustrations of all these conditions will readily occur to any one who has seen much of hysteria. Therefore, I think we can safely say that hysteria is a neurosis involving the great sensory-motor reflex function of the cerebro-spinal apparatus; that the typical form (aboulia) is a disturbance of the higher (cerebral) sensory-motor reflex as much as are the hysterical symptoms caused by a disturbance in the lower (spinal cord, ganglionic) sensory-motor reflex arc. Being a neurosis, involving all the cerebro-spinal reflexes, it is easily seen why hysteria should mimic all organic diseases involving the same reflex arcs.

From the above standpoint, the treatment of hysteria becomes plain. In the lower form of the disease all extraneural sources of irritation should be sought for and removed so as to restore the integrity of the lower reflex arcs. In the higher form, a new set of different impulses and new motives should be

awakened so as to restore the equilibrium of the higher or cortical sensory-motor reflex arc. Of course, heredity is a tremendous obstacle to overcome, but is not altogether insurmountable. Given, therefore, all measures to restore the physical condition, nutrition, etc., of the tissues involved, the treatment of hysteria resolves itself into the study and correction of the patient's sensory-motor reflexes. This involves so many obvious details that I will not occupy your time now in rehearsing them.

Reliance Building.

THE RELATION OF NEURASTHENIA TO INSANITY.

Presented to the Section on Neurology and Medical Jurisprudence at the Forty-ninth Annual Meeting of the American Medical Association, held at Denver, Colo., June 7-10, 1898.

BY JOHN PUNTON, M. D.

KANSAS CITY, MO.

The vast increase of our knowledge of the nervous system and its application to disease has been found to be most useful in the correction of certain former erroneous inferences. Hence a complete revolution has taken place in our knowledge of its pathologic states, which has also been the means of greatly enlarging the range of its organic lesions, at the same time materially limiting the scope and significance of its so-called functional affections. In spite of our grand success, however, in unraveling the secrets of the morbid changes in both structure and function of the neuron, much still remains to be done before we can successfully cross the Rubicon that separates organic lesions from those that are of purely functional origin.

This uncertainty of our knowledge has led to the formation and maintenance of a false system of nomenclature which not only confuses but greatly hinders the progress of scientific nosography. Hence many terms have come into general use which at the time of their advent were very convenient screens to shield our ignorance, but as our knowledge increased the scope of their power and significance was greatly reduced and limited, until today a larger and fuller knowledge renders many of them futile and actual misnomers. Others again embody a generalized morbid state or condition which later investigation renders capable of scientific classification, thereby greatly limiting their former power and significance, and unless the physician is fully aware of the changes wrought by such advance, he is greatly handicapped in his interpretation of the term, and his skill in diagnosis proportionately suffers. In no branch of medicine are such mistakes more common and conspicuous than those found to be associated with lesions of the nervous system. Nor is this strange when we remember its complex mechanism and the difficulty experienced in mastering the details of its scientific study in health and disease.

One of the most striking and widespread examples of mistaken identity in the true interpretation of the significance of the term is found associated with the morbid condition designated as "neurasthenia." I doubt if there is a more common and serious affection of the nervous system that is more generally misunderstood by the profession at large than this *fatigue-neurosis*. It is surprising to find the gross indifference manifested on the part of many physicians toward its real nature and character. Not only do they treat neurasthenia carelessly, but they refer to it

slightingly, and imply both by word and conduct that they believe the patient to be a malingerer, and that his sufferings are entirely false and even conjured for the occasion. It will, therefore, be the purpose of this paper to try and correct such erroneous inference as well as place it upon its true scientific basis.

The term "neurasthenia" was supposed to have been first used by Dr. Beard in describing a general morbid weakness or exhausted state of the nervous system. Later investigations, however, prove that his claim to priority in its use was an erroneous one. To Dr. VanDusen belongs the credit of using it as early as 1867 in his valuable paper entitled "Observation Upon a Form of Nervous Exhaustion, or Neurasthenia Culminating in Insanity," which appeared two years earlier than Beard's famous monograph. It has since been shown, however, that neither of these physicians invented the term, as it can be found in Dunglison's Medical Dictionary published in 1833. Notwithstanding these facts, the medical profession is under lasting obligations to Dr. Beard for the persistent manner in which he emphasized the importance of its study, thereby acquiring for himself an enduring monument in medical science. Prior to his labor in this direction, much confusion prevailed in the interpretation of a large group of symptoms which were fundamentally dependent upon a morbid weakness of the nerve centers, but which had been previously ascribed to disease of the various visceral organs involved, such as perverted conditions of the kidney, liver, stomach, uterus, etc. The result of Beard's work, however, led to a more thorough systematic study of its pathogenesis, which is still in progress, and the conclusions so far reached warrant the assertion that expresses an affection which does not limit itself to any part of the nervous apparatus, but affects it as a whole. Hence it is an extremely generalized condition, and often associated with other functional and organic diseases.

Its extremely generalized character may therefore affect the brain, spinal cord, peripheral nerves, the visceral organs, and indeed all parts of the human organism subject to nervous innervation. Consequently its symptomatology is exceedingly extensive and varied. This wide range of involvement has led to much confusion and is the responsible agent for the vague, ill-defined notions entertained by many concerning the true nature and character of neurasthenia; some physicians even going so far as to deny its existence altogether as a clinical entity. Laying aside all controversy, the consensus of opinion today by those most competent to speak declares that neurasthenia in its quintessence is a true fatigue neurosis characterized with an increased morbid reaction of the ganglionic nerve centers to all kinds of impressions, both mental and physical, whether slight or profound; producing an excessive nervous weakness and nervous irritability, which constitute its chief cardinal symptoms. Moreover, recent investigation demonstrates that while the various symptom groups occurring in neurasthenia are numerous and differ widely in detail, yet there are always present certain essential features that constitute a well-defined clinical syndrome. These have been termed by Charcot as neurasthenic stigmata.

All authorities agree that the cardinal symptoms of neurasthenia present well-marked evidence of weakness and irritability of the nerve centers which in themselves are expressive of fatigue. Weakness and

irritability of the nervous mechanisms that preside over the various bodily organs are, therefore, the chief clinical phenomena, belonging to any and all varieties of neurasthenia. These may present themselves in all degrees of intensity and are usually accompanied with other symptoms which denote the particular functions of the nervous system that are involved. Hence we may have involvement of the motor, sensory, reflex, trophic, secretory, visceral and psychical mechanisms which furnish a wide and varied range of clinical phenomena. But it matters little what part of the nervous apparatus is included in the pathologic process, the two dominating factors that are present and common to all varieties, and that which defines neurasthenia as a separate and distinct clinical entity are weakness and irritability of the various nervous functions involved. They are, therefore, properly regarded as the essential primary or fundamental symptoms of the lesion while all other associated clinical evidences of involvement are termed secondary or adventitious symptoms. These latter may be the outgrowth of the former and are simply parts of a well-defined harmonious entity.

Neurasthenia, therefore, presents two great classes of symptoms, viz: primary and secondary or adventitious, which may affect both the physical and mental constitution in varying degrees of intensity. The skill of the physician, therefore, in its diagnosis depends upon his ability to differentiate the one from the other, and upon this largely hinges the prognosis. Moreover, neurasthenia is variously classified by different authors according to its etiology, symptomatology or the apparent seat of lesion. Hence we may have cerebral, spinal, traumatic, sexual, toxic, reflex and many other forms of the disease. While no doubt this method has some advantages, yet it often proves very confusing and misleading.

A classification that recognizes neurasthenia in its entirety is to my mind, therefore, much preferable, and from this standpoint it can be reduced to two classes, viz: 1, complicated; 2, uncomplicated neurasthenia. In the former it may be found associated with many functional as well as organic diseases, such as epilepsy, syphilis, malaria, gout, rheumatism, uterine disease, hypochondria, sexual perversion, insanity, as well as many other morbid conditions. In the latter it presents itself by a conspicuous absence of any such complications, in which case it is known as simple or uncomplicated neurasthenia. The effects of either class, however, produce symptoms which may be referred to both the physical as well as mental constitution of the individual, and present a wide range of clinical phenomena that are, for the most part, subjective in character. While it is true that much speculation has been indulged in relative to its pathology, we are still compelled to admit that so far we are unable to positively declare what the actual changes of the nervous elements are in neurasthenia.

The two important symptoms, viz: morbid irritability and morbid weakness of the nerve centers, have been shown by Hodge to be due to changes in the nerve cell itself, and that the lesion of fatigue is loss of cellular substance involving the nucleus, protoplasm and even the capsule itself. According to Decum, this waste of nerve substance had been demonstrated by Mosso to alter the constitution of the blood, producing a true toxemia that strongly inhibits the physiologic action of the nervous elements distributed to the voluntary muscles and

other organs of the body. Let this be as it may, it is certain that the element of autotoxemia enters largely into the production of neurasthenia, and often gives rise to tissue changes that are commonly found associated with its more severe forms. The continued results, however, of nerve strain from any cause, that form so prominent a factor in American business, social, political, and professional life, operate upon the physical and mental organization in such a manner as to exhaust strength or vital force more rapidly than recuperation takes place. Consequently nervous exhaustion or neurasthenia ultimately ensues. More especially is this found to be true of persons inheriting a neurotic diathesis, as this renders them more susceptible to the baleful influences of the common causes of neurasthenia. Excess and abuse, of any and all kinds, with faulty methods of living, operating upon such an individual are recognized by all authorities to be potent factors in the production of neurasthenia. Dana claims that the causes of neurasthenia can be reduced to two agents, viz: bad heredity and foolish living (*Twentieth Century Practice*.)

The reduced nervous energy that results from such causes seriously affects the visceral organs and nutritive functions of the body, which is expressed clinically by a marked weakness or inaction as well as want of vigor of all the bodily processes. A feeling of bodily illness is thus engendered that attracts the attention of the patient to himself and ultimately forms the basis of morbid fears or nosophobia. This again leads to the development of despondency, petulance, irritability, selfishness, impatience and vacillating conduct, all of which are marked features of the formative or incipient stage of insanity. All authorities agree that incipient insanity is attended with physical and mental changes that are indicative of nervous exhaustion, and that clinically they are expressed by a diminution or want of vigor of all the bodily processes. Moreover, despondency and nervous irritability are also marked features of early insanity.

The relation of neurasthenia to insanity, therefore, cannot be overestimated; indeed the relation one bears to the other in a large number of cases is so very close as to almost establish a true equivalency. Kirchoff has clearly shown that certain insanities, such as melancholia, mania, paranoia and paralytic dementia may develop upon a neurasthenic basis, while Chapin, in his recent work on *Insanity*, just published, also declares that the larger proportion of hospital admissions received in an acute stage of insanity have a history of neurasthenia. He therefore fitly styles it the "soil out of which insanity develops." Unfortunately, too often the close relation that exists between neurasthenia and insanity is entirely overlooked and even ignored. Consequently many a curable case becomes incurable by failure on the part of the physician to recognize its true nature and character. Moreover, its close relation to hysterical states often leads the physician to treat it with contempt, under the mistaken idea that the barometric changes from day to day indicate a fraudulent basis. Nothing could be further from the truth, as there is plenty of evidence in every genuine case of neurasthenia to explain its fluctuating tendencies even in its most simple and uncomplicated forms. One of the most important signs of neurasthenia becoming complicated with mental disorder is the manner in which the feelings, thoughts and actions of the patient absorb his entire attention. This self-consciousness

is a marked feature of many forms of neurasthenia and betrays the serious invasion of the higher mental faculties in the progress of the malady.

These concepts have been variously designated by different authors as obsessions, impulsions, imperative concepts, besetments and fixed ideas. They usually consist, however, of a general feeling of anxiety, which amounts to morbid doubts and fears that later lead to impulsive acts. They irresistibly force themselves upon the individual, dominating his every thought, word and deed. In their more severe forms they constitute the various phobias, but as they present themselves in all degrees of intensity, it is the degree combined with their persistency that indicates their true seriousness. For convenience of study Regis (See *Manual Mental Medicine*, p. 262) has divided them into three classes, viz: 1, those characterized by indecision, of which all kinds of morbid doubts are typical; 2, those characterized by all kinds of morbid fears; 3, those characterized by morbid propensities or irresistible tendencies. Each of these is again subdivided. For instance, Ball has divided the first class, or doubters, into five subdivisions, according to the nature of their predominating ideas. Hence we have: 1. "The metaphysicians, who are especially haunted by abstract questions of all kinds, such as doubts concerning heaven, hell, the world, the deity, etc." 2. "The realists, who constantly revolve in their thoughts the lower and base details of objects, such for example as the conformation of the genital organs, copulation, etc." 3. "The scrupulous, whose doubts pertain to forms of religion, such as accusing themselves of committing the unpardonable sin, or of some theft, etc." 4. "The timorous, who are fearful of committing some indelicate action by even allowing their clothing to come in contact with that of others, etc." 5. "The counters, whose doubts are manifested under the form of irresistible enumeration." Such patients never get through counting different objects, such as door knobs, the houses on the street, or their numbers, etc."

The second class, or those suffering from morbid fears or phobias, is divided into three subdivisions:— 1. those who have a morbid fear of all kinds of objects. Its expression is extremely varied, and may involve such articles as glass, knives, pins, guns, thunder, flowers, besides certain kinds of food and drink. 2. Those who have a morbid fear of places, elements or diseases. Such patients are morbidly fearful of high places, bridges, streets, churches, theaters, rivers, beside a dread of all kinds of diseases, such as heart disease, liver disease, cancer, etc. 3. Those who have a morbid or irresistible propensity to steal, lie, cheat, drink, blaspheme, set on fire, or abuse the sexual organs. All of these various states are ably shown by Regis to be due to lesions of the will and are often associated with neurasthenia.

In a limited degree they are commonly present in health; indeed very few of us escape the presence of doubts, fears or impulses as isolated sudden thoughts, but which are controlled by the dominating power of inhibition. For instance, it is a common experience for persons looking from a height to be tempted to jump down; or in walking on the street are suddenly seized with a desire to count the houses or numbers on the doors, etc. But these sudden impulses are easily resisted or controlled, but when they appear as a complication of neurasthenia, they are often morbidly persistent and get beyond the control of the

will. In their exaggerated forms, they therefore constitute a serious symptom and may become the dominant feature of a grave form of insanity. In all cases, however, where their presence can be demonstrated, they are to be regarded as marks of true degeneracy, often remaining latent for years, to be brought to the surface by some sudden or severe shock to the nervous system; such as trauma, or severe mental and physical strains, beside excesses of all kinds. That such states also often accompany insanity is generally recognized, but I repeat it is their intensity combined with their persistency that indicate their true seriousness. Moreover, there can be little doubt that certain crimes are due to such sudden impulses which arise in the minds of persons who are not ordinarily regarded as insane, and which the subjects are wholly unable to resist. Hence they are truly irresponsible and should be given the benefit of the doubt. From the fact that such symptoms are so frequently seen in both neurasthenia and insanity, the close relation that exists between the two cannot be overestimated. Indeed, all the evidence proves conclusively that neurasthenia in its more profound types presents many symptoms in common with true insanity, and the line of demarkation that separates the one from the other is at times as dimly drawn as that which exists between sanity and insanity, physiology and pathology.

Moreover, the teaching of our text-books in regard to their differential diagnosis is often very misleading, for we are taught to believe that in neurasthenia the morbid fears can be removed by a process of reasoning, and that the patient can be convinced of his mistaken ideas; while in true insanity no amount of reasoning succeeds in convincing the patient of his mistaken notions. If this was taken as a criterion, many a neurasthenic patient would be regarded as suffering from insanity, when as a matter of fact his neurasthenic condition had not reached that extreme degree of mental impairment that is synonymous with true insane delusions although the morbid fears apparently resist all forms of reasoning. It must be confessed, however, that when the morbid doubts or fears reach a certain degree of intensity, combined with persistency, they then often become the equivalent of true insane delusions and should be treated accordingly.

That many cases of neurasthenia become thus complicated is clear to all, and the importance of the close relation that exists between neurasthenia and insanity, I repeat again, cannot be overestimated; indeed it often requires at best much practical knowledge and experience to recognize the appearance of one and the disappearance of the other.

In conclusion I wish to add that in the preparation of this paper I desire to acknowledge my indebtedness to such authors as Regis, Dercum, Dana, Gray, Kirchoff, Clouston, Blandford, Diller and many others, beside cullings from recent neurologic and psychological journalistic literature.

DISCUSSION.

Dr. MEYER—The daily work in the hospitals for the insane leads one continually to the following dilemma: that we either have to give up making diagnoses and take everything as diffused manifestations of sickness or disease, in which case we would be inclined to let neurasthenia be just one of the initial symptoms of insanity—something that may or may not go over into insanity; or, we can take the plan which I am more inclined to follow for clinical reasons, viz., endeavor to

single out those forms of neurasthenia which we know are initial stages of certain forms of disease, and try to keep those separate and apart from neurasthenia that always remains neurasthenia without ever going over into insanity. Dr. Maclean has made a classification of insanity in which he takes neurasthenia to be the initial symptom of all general insanity, even of general paralysis. If we do that we give up all clinical method. The fact that symptoms in the beginning of general paralysis may be those of neurasthenia, should not induce us to say that that is the same neurasthenia which may exist independently and never go over into general paralysis except after previous syphilitic infection. For clinical reasons, therefore, in working out problems, I should hesitate very much to allow neurasthenia to take quite as broad a field as Dr. Puntton gave it. We have to distinguish besides, the simple neurasthenic constitution: then the real fatigue neurosis; then the initial stages of definite forms of disease, such as general paralysis, and such as periodic insanities or any special form of insanity. I admit that it is at present almost impossible to say at the start in certain forms of neurasthenia what it is. I think that it is easy enough to distinguish the constitutional neurasthenia from an acute fatigue neurosis; it is also rather easy to distinguish neurasthenia that is the beginning of general paralysis; but, nevertheless, there will be a great number of cases that will lead us into the habit of looking upon neurasthenia as that diffused field into which we are inclined to throw anything that we can not classify anywhere else.

Dr. H. S. DRAYTON of New York—My first acquaintance with this Protean form of neurosis was derived from reading certain pamphlets by Dr. Beard of New York. I think it is to Dr. Beard that we owe the term "neurasthenia." Some eighteen or twenty years ago he published a volume entitled "American Nervousness," in which he described a train of symptoms that seemed peculiar to American civilization, and a little later he came out with this term "neurasthenia." He described the peculiar category of symptoms which were included under this form as having a particular relation to our American climate and civilization, and since I have heard a good deal about the Denver climate of late I have been wondering whether or not there is anything here that is at all curative of neurasthenia. Now it seems to me that in the effort to make a differential statement so that we can determine at all what there is peculiarly its own in neurasthenia, we might ascribe to that form of nerve disease a capricious category of symptoms; that is, that neurasthenia is indicated more by caprices of habit, caprices of mental expression. The causative factors are to be looked at from the point of view of the individual's heredity and life, as in all forms of nerve disease. Not long ago, Dr. Spitzger, whose name I think is very well known in this circle, delivered a very elaborate opinion with regard to the difference to be drawn between neurasthenia and melancholia, and in a nutshell, he seemed to be of the opinion that most neurasthenic troubles were traceable to specific cause. Looking at the subject from one aspect, that is, the number of cases of young people affected, young men especially affected by neurasthenia, it strikes me from my own observation that the great majority of these causes are found among the comparatively young; so that it may be termed a trouble or affection of those chiefly under 40 years of age. Now, can we fairly discriminate; I might ask, can we draw a very fine line of demarcation between neurasthenia and melancholia? It strikes me that we cannot. From what I have heard from the late reader to that most admirable paper, my opinion is confirmed in regard to the relation of neurasthenia to insanity. Accepting that view, we see the necessary relation to melancholic patients.

Dr. TOMLINSON—The more experience I have in the observation of cases of insanity the more am I confirmed in the conclusion that it is about time to call a halt in multiform classifications and diagnoses, and while we can say that the average case of insanity presents certain physical conditions which have for their outward manifestations the characteristics of neurasthenia, still, at the same time, this is present in all cases of insanity, and there is no difference between the neurasthenic manifestations of an insane person and the neurasthenic manifestations of a person who is not insane. So far as trying to make a relation between them is concerned, it only ends in confusion. While the insane person may in the earlier stages, or may, all through the outbreak of mental disturbance, manifest neurasthenic symptoms, still the neurasthenic symptoms have nothing to do with the insanity, nor does the insanity have anything to do with the neurasthenia. It is a matter of

relation rather than of causation. It is not those cases in which neurasthenia is most marked that afterward become insane. The same holds true with regard to the other conditions which are supposed to differentiate forms of insanity, and so far as their practical care and treatment are concerned, in the effort to make a diagnosis and to put this case or that case into a marked classification, this has a tendency to obscure and interfere with our treatment. Furthermore, there is not, so far as I know, any pathologic difference, and we have to go further back in the history of the case to determine just what the significance of these manifestations is. It seems to me it lies in the difference of degree of instability or defect in the individual who becomes insane or neurasthenic, and that we can get a clearer and more definite idea of the subject by recognizing the neurasthenic as representing a certain degree of instability. So long as we do not bear this in mind, the more we try to classify, and the more we try to understand these cases, the more will we become confused. In my own work I have practically given up attempting to make a diagnosis or attempting to classify one case from another, because I see that one case, although it may manifest a certain number of symptoms which might place that individual case in a certain classification, still during the period of the illness or mental disturbance there will be a whole host of other symptoms manifest themselves which would seem to put the case in another category. So, while it may for a time be of interest to classify them, so far as the patient is concerned, it is important to recognize that it does not make any difference what their condition is—what we have to deal with is the insanity, and back of that is the degree of the defect of the individual, and upon the degree of that defect will depend the diagnosis.

Dr. HORPE—I believe that the view which the individual members hold depends upon the standpoint from which they see their cases, whether in insane asylums or in general practice. Personally I have never seen but one case of neurasthenia pass into insanity. I believe that these cases are very sharply divided and identified, and I do not think that the pure form of neurasthenia will ever pass into insanity. For instance, take that class of neurasthenics who have fixed ideas. Their judgment may be wrong in this respect, but in all other respects it is right. It is not so much an error of judgment as it is based upon a fear which can be classed among the phobias or neurasthenias which occur in those cases of neurasthenia which are constitutional in character and based upon hereditary defects. I believe there is a very sharp line of demarcation between neurasthenia and melancholia. It is true that in neurasthenia we have depressed states; but that in my estimation does not constitute melancholia. I believe that the fundamental idea of melancholia is the idea of self-accusation: that the patient takes some point in his past history, real or imaginary, which he accuses himself of having committed, and which he looks upon as the cause of all his mental pain and suffering, whereas we never see that in the depressed form of neurasthenia.

Dr. ESKRIDGE—I shall have to differ from my friend Dr. Hoppe. I have seen quite a number of cases of neurasthenia pass into melancholia. During the past fourteen years I have been able to follow my cases from the clinic room and the office to the insane asylum, having the privilege of visiting patients there from time to time during that period. I have thus been able to follow a great many cases of neurasthenia. There is a very close relation between neurasthenia and insanity. I doubt very much whether any one can positively say that a given case of neurasthenia will not pass into melancholia. I doubt very much whether anyone can say with any degree of certainty that this particular case of neurasthenia is not melancholia. A great many cases of melancholia begin with neurasthenic symptoms. Whether that passes into insanity depends upon several causes, but two of the principal are the hereditary condition of the patient—that is the nervous stamina—and the man's hands into which the patient falls. There is certainly a very strong personal element in treating these cases of neurasthenia and beginning cases of melancholia. That person who can inspire confidence; that person who can make his patient feel that he or she is going to get better, whether he is a good physician or not, will have more effect than a second physician who has not personal magnetism. I do not believe that we ought to try to draw a hard and fast line between neurasthenia and melancholia.

Dr. JOHN PUNTON, Kansas City—I have nothing more to say except that I appreciate highly the kind manner in which my paper has been received, and from the remarks that have been made it is evident that we are not altogether settled in our opinions as to whether there is a relation between neurasthenia and insanity or not. As far as I am concerned, my position is the same as Dr. Eskridge's.

A CLINICAL STUDY OF MULTIPLE NEURITIS IN YOUNG CHILDREN.

Presented to the Section on Diseases of Children, at the Forty-ninth Annual Meeting of the American Medical Association, held at Denver, Colo., June 7-10, 1898.

BY ANNE STURGIS DANIEL.

PROFESSOR OF PEDIATRICS WOMAN'S MEDICAL COLLEGE OF THE NEW YORK INFIRMARY.
NEW YORK CITY.

The following brief clinical studies of multiple neuritis embrace only those cases in which were found motor and sensory paralysis of symmetric development, but do not include that form of neuritis which affects only the muscles of the palate or of the nose, as shown by regurgitations of fluids, with nasal voice or those cases affecting only the ocular muscles.

Diphtheria is undoubtedly by far the greatest cause of multiple neuritis. Comparatively few cases are caused by the other infectious diseases. Smallpox is not infrequently a cause of the disease, but I have seen no mention made of chicken-pox giving rise to the disease. I, unfortunately, have one case to report of the production of the disease by arsenic given during the course of treatment of chorea. I have twelve cases to report, the causes of which were: arsenic administered for chorea, 1 child; diphtheria, 9 cases; varicella, 1 case, and measles 1 case. Seven children were cured, 5 died. In none of my cases were the sphincters involved; in all cases there were some deviations from the normal mental condition of the child. This last symptom I have seen little stress laid upon. The first symptom noticed was simply a weakness of the extremities, followed rapidly by inability to stand or walk—the motor paralysis appearing first, followed at once by the sensory paralysis, the recovery being first of the sensory and later of the motor paralysis.

No allusion was made in medical literature of paralysis following diphtheria until the end of the 16th century, the first mention being made in 1580. Ghisi, in 1747, describes an attack in his own son, and adds that he "left to nature the cure of the strange consequences." The first description of the disease in America was given by Dr. Bard of New York, in 1771. Few authorities describe multiple neuritis in children, although diphtheretic paralysis was described long before the disease was considered to be a neuritis. In looking over the statistics of paralysis following diphtheria, I find no distinction is made, or in only a few instances, of paralysis affecting the throat only and a general multiple paralysis. In the collective investigation of the American Pediatric Society, of 189 cases, the paralysis was general in 8 only. They report 3384 cases with 9.7 per cent. followed by paralysis. Various other estimates are given of from 5 to 15 per cent. All authorities agree as to the rarity of death, although one authority thinks physicians are too optimistic in regard to the mortality. Of my 9 cases, 3 were treated during the attack of diphtheria with antitoxin; of these three, 2 died. Five of the 9 children were treated during the attack of diphtheria. In 7 cases the Klebs-Loeffler bacilli were found; the other two occurred before the discovery of the bacilli. The ages varied from 23 months to 12 years.

Case 1.—Willis S., the youngest child, 23 months, had an attack of diphtheria, moderately severe. One week later there was hoarseness followed by regurgitation of fluids through nose, nasal voice, and internal strabismus of both eyes. At the end of the first week the child was unable to stand alone, or walk, pain over track of nerves, most marked in the lower extremi-

ties, anesthesia, as shown by the indifference to prick of pins; the temperature test was not applied; the child lacked its normal intelligence. The symptoms increased rather in extent than intensity, the muscles of the neck becoming involved. The rectal temperature varied from 101 to 104.5, with at the end 106. Death occurred in a spasm at the end of the fourth week from the first appearance of the sore throat.

Case 2.—Joe S., 4 years; seen on the eighth day of diphtheria. Klebs-Loeffler bacilli found, nose, pharynx and tonsils involved, moderately severe attack; throat normal and free from bacilli on the thirteenth day after the first symptoms. Thirty-one days after the first appearance of the sore throat, or eighteen days after recovery from the diphtheria, nasal voice and regurgitation of fluids were noticed, and the child walked with difficulty; this increased in severity, the child became unable to either stand or walk alone, pain on pressure over the nerves of the lower extremity, with anesthesia. The muscles of the trunk and neck were not involved. The child again began to walk fifteen days after the symptoms of nasal voice and regurgitation were noticed, with complete recovery shortly after.

Case 3.—Sara N., had a mild attack of sore throat, according to the history of the mother, from which she recovered. In the fifth week after, nasal voice and regurgitation of food began. The child complained of being tired and disinclined to walk; this gradually increased, and at the end of four weeks she was suddenly seized with pain in all the extremities, and shortly after was unable to stand, walk, sit or hold head up: marked tenderness and anesthesia in all extremities. The temperature test showed great pain when heat was applied, but she insisted that the cold made her feel much better. The tenderness over the track of the nerves was intense; the temperature varied from 101 to 104.5; there was gradual loss of intelligence. Five days after she complained of severe pain, the physical signs of broncho-pneumonia were found; death occurred in the ninth week from the first symptoms of sore throat.

Case 4.—John K., 3 years; recovered from a mild attack of chicken-pox about July 1. On the 7th the child was attacked by laryngeal diphtheria. Antitoxin was given, and the child was completely recovered by July 14; the bacilli persisted until July 31. August 1 the mother noticed the nasal voice and a very slight regurgitation of fluids—on the 7th the child held the head to one side, staggered when attempting to walk, and fell down frequently; four days later was unable to stand alone; anesthesia marked; temperature test showed heat felt over a part of both limbs—of lower extremities, less on upper and on the trunk. Child at times seemed delirious, intelligence very much below his normal, died suddenly, apparently from cardiac paralysis on the eighteenth day after the first regurgitation of fluids.

Case 5.—Mild attack of diphtheria, December 30. Antitoxin given; complete recovery on the eighteenth day. February 7, without previous regurgitation of food, child began to limp, and fell down a great deal, complained of pain in the legs; four days later could walk only by dragging the feet, and at times crossed his legs during locomotion; could not stand nor walk alone; marked pain over track of nerves, with marked anesthesia of both legs; no reaction to cold temperature test. Slight reaction to heat; upper extremities normal; could sit alone, but only a few minutes. On the sixteenth day internal strabismus of the left eye was noticed; on the twenty-first day attempted to walk; twenty days later completely well. The intelligence of this child was less affected than the others.

Case 6.—Annie P., 9 years. Early in November had an eruption on the hands, the nature of which was not known. No attention was paid to this, and about December 1 complained of inability to walk, and regurgitation of fluids and nasal voice. When seen a few days later could neither stand or sit alone; tenderness over track of nerves, patella reflex nearly absent. The symptoms remained about the same for a month, then marked change in the intelligence, utterly unable to move the lower limbs or hold the head up; tenderness over track of nerves much more marked, with marked anesthesia. Entire absence of patella reflex; slight atrophy of lower limbs; could not swallow even solid food without choking. All symptoms continued to increase in severity; intelligence became more affected; there was anesthesia of all limbs and of the throat, as shown by the indifference to the introduction of the stomach tube, this being at first much resisted. The disease lasted from November 1, the time of appearance of the eruption, to January 29, when death occurred apparently from cardiac paralysis.

Case 7.—George Mc., 5 years. In the latter part of March had a mild sore throat; well in a week. One month later child began to behave strangely and staggered when walking. This slowly increased, then nasal voice and regurgitation of food.

In ten days from first symptoms, child decidedly idiotic. Could not sit, stand or walk, even with much assistance. Pain over track of nerves, anesthesia most marked in the lower extremities. Patella reflex absent. On the fifteenth day very slight improvement, which gradually increased and the child was entirely well, with his usual intelligence thirty days later.

Case 8.—Charlie S., 4 years. Diphtheria September 1, moderately severe; treated with antitoxin; made a good recovery. October 5 child became sleepy, some regurgitation of fluids; two days later marked tenderness over track of nerves in the lower extremities; unable to stand alone or walk; four days after the first symptom of regurgitation, child unable to hold head up or sit alone; very marked tenderness over the track of the nerves in the lower extremity, to a less extent in the upper extremities; anesthesia marked over lower limbs, less over upper; in parts of chest and abdomen marked anesthesia; much muco-purulent discharge in mouth and throat; intelligence much diminished; the lungs showed signs of a general broncho-pneumonia, and very numerous pleuritic rales. The patella reflex entirely absent. The anesthesia and paralysis became marked, and death occurred on the ninth day from the first symptom of regurgitation and weakness.

Case 9.—Christine N., 6 years. January 6, mild attack of diphtheria, from which she apparently completely recovered. February 18, feverish and vomited; complained of much pain in both legs and was unable to walk; admitted to the New York Infirmary for Women and Children; absence of patella reflex on both sides; marked pain and tenderness over the track of the nerves, with very marked anesthesia to prick of pins and to the heat test; slight reaction to cold; upper limbs and trunk were normal; both feet extended; neither nasal voice or regurgitation of fluids; child not so bright as she is normally; can not stand alone nor take a step alone. Symptoms gradually decreased and child was well, with normal sensation and no paralysis March 27.

Case 10.—Nettie B., 9 years. February 29, eruption of chickenpox, which followed a normal course. Two weeks later child was taken out by an elder sister and complained of being too tired to walk; was out a long time and returned complaining of pain in both legs and inability to stand or walk alone. When seen the next morning there was marked tenderness over the track of the nerves, diminished patella reflex. The inability to walk increased; pain became more marked with noticeable anesthesia; nearly entire obliteration of patella reflex. Symptoms remained about the same; child could walk with great difficulty when supported. The disposition was extremely "cranky," the reverse of her normal condition. The upper extremities were at no time involved. At the end of three weeks the symptoms diminished in intensity, and gradual improvement took place. The child was perfectly well by May 15.

Case 11.—Rose B., 11 years. Entered the New York Infirmary, February 20, with a mild attack of chorea; by March 22 there had been little improvement in the symptoms and 5 minims Fowler's solution was ordered to be given every three hours day and night, a minim to be added each day. On March 29 she was taking 11 minims, when she vomited and the drug was discontinued for twenty-four hours. April 7, she was taking 119 minims, when a red papilla eruption was noticed, and symptoms of gastric catarrh, and the note was made that the arsenic had very little effect upon the chorea, so it was discontinued. April 13, the child seemed not to see and hear well. On the 19th very little twitching; May 2, no twitching. During this time the child had been disinclined to walk; had not seemed as intelligent as usual. May 12 the gait was very irregular and uncertain; dragged both legs; there was marked tenderness on pressure over the nerves; on the 21st utterly unable to stand alone, much pain over nerves, marked anesthesia in lower limbs. The symptoms of neuritis reached their height at this time and began slowly to disappear. June 4, began to walk a little with assistance; July 9 walking normally; no tenderness over the nerves; anesthesia had disappeared; discharged July 14, with no trace of either neuritis or chorea.

Several cases similar to Rose B. are found in medical literature, but the dose at the time of the development of the neuritis was smaller. This child received in the last twenty-four hours of the medication Fowler's solution $\frac{1}{3}$ iiss, or $1 \frac{3}{5}$ gr. arsenious acid. One case is reported by Dr. Roberts, in which the child received 66 minims in twenty-four hours in three doses. In my case the symptoms of neuritis at first closely resembled those found at the end of chorea. The weakness and paralysis, with the anesthesia, appeared abruptly. The upper extremities were not

affected, but the trunk muscle seemed weak; the child could sit alone only for a few moments.

Case 12.—Anna J., 4 years. December 2, eruption of measles in the normal manner. December 3 the child refused to speak; seemed apathetic. A day or two later would smile and laugh without reason. Seven days after the first appearance of apathy the child could neither sit nor stand alone, cried when placed on her feet; marked tenderness over the track of the nerves in the lower extremities, with anesthesia. Between the third and the seventh day the symptoms gradually progressed and reached their height on the seventh day, remaining the same until the eleventh day, when she began to notice a little, and made her desires known by crying and pointing to objects, and attempted to stand but cried when placed on her feet. On the sixteenth day made an attempt to speak, but seemed unable to articulate; tried to walk on the nineteenth day, and was able to articulate; could stand alone and walk, but inordinately, on the twenty-second day; by the twenty-eighth day could speak distinctly, if not excited, put words into sentences, walked about but staggered some; pain over track of nerves and anesthesia nearly gone. Child walked normally at the end of six weeks; spoke as well as before illness at the end of three months.

In none of my cases were the sphincter muscles attacked. The family history in all cases was unimportant, except in the case of George N., whose parents are alcoholic, and Charlie S., whose mother died of tuberculosis during the child's attack of diphtheria. All the children except Nettie B., were tenement-house children. The sanitary surroundings of John K. were especially bad; the child lived in rooms into which daylight came in midsummer only from 10 A.M. to 3 P.M.

The differential diagnosis was made chiefly from Landry's paralysis, but in this the paralysis begins in the legs, spreading from one to the other, then to the upper extremities; in my cases the paralysis began in both legs at the same time. In the cases of diphtheria the nasal voice and regurgitation preceded the loss of power in the limbs; in none of my cases was there a question of poliomyelitis. The question of Friedrich's disease, I think, could be thought of only in the case of the child with measles, the only resemblance being the disturbance of speech. From myelitis the diagnosis was made from the symmetrically located pain, and no involvement of either bladder or rectum, and in each case the distinct history of a preceding infectious disease, except in the case of Annie P., in which the diagnosis of an infectious disease was uncertain, but with the first symptoms of inability to walk, was present the regurgitation of fluids and nasal voice, which are not found in myelitis. The treatment consisted of strychnin, either by the mouth or hyperdermatically; stimulants when indicated.

THE RECOGNITION AND TREATMENT OF EARLY MYXEDEMA IN CHILDHOOD.

Presented to the Section on Diseases of Children, at the Forty-ninth Annual Meeting of the American Medical Association, held at Denver, Colo., June 7-10, 1898.

BY FREDERICK BIERHOFF, M.D.

Clinical Assistant, Department of Pediatrics, College of Physicians and Surgeons.
NEW YORK CITY.

That myxedema is not a disease *per se*, but a symptom, or collection of symptoms, dependent upon the absence, or upon a diseased condition of the thyroid gland, is now generally accepted to be a fact, the degree of severity of the symptoms depending upon the extent to which destruction of the secreting portion of the gland in question has taken place. That cretinism, myxedema and goiter (so-called) are but

variations of the one disease, is a view that is gaining adherents, as closer study into these conditions reveals the similarity in many of their symptoms, and the excellent results obtained in their treatment by the same therapeutic means. Sir William Gull¹ first defined myxedema as "a cretinoid state supervening in adult life in women," and drew attention to the similarity between myxedema and cretinism, expressing his opinion that both are allied. Ord² and others have also pointed out this similarity.

The accepted cause of the conditions is either absence of, or disease of, the thyroid gland. If the gland is congenitally absent, we get the condition known as true cretinism, either congenital or sporadic. When changes in the gland occur early, we have the cretinoid condition, or early myxedema; when these changes occur in persons who have attained full physical

trophic stage of a cirrhosis. Where this enlargement or hypertrophy is not general, we probably have to deal with a simple hypertrophy of the functioning portion of the gland consequent upon changes in another portion. Murray,⁴ in his excellent article on myxedema, says, in dwelling upon the differences between the varieties of myxedema: "In this connection it must be borne in mind that the actual size of the thyroid gland is not necessarily an indication of the amount of functional activity of which it is capable. A considerably enlarged gland may, from the nature of the structural enlargement, be just as incapable of carrying on its function as an atrophied gland." At the same time, the presence of a goiter does not of necessity presuppose myxedema, since that portion of the gland which remains may suffice in secretory power to continue the patient's normal

Sadie K.

Sadie K.

growth, we have myxedema. So much of value has been written of recent years in relation to the first and third divisions mentioned above, that it would be presumption on my part to add to or criticise; but in relation to the second, or type of early myxedema, it may be pardonable to present a few cases for consideration.

It was the occurrence of goiter in cases presenting some of the symptoms of myxedema, but in which growth had not been arrested, which first drew the writer's attention. In the adult, myxedema is nearly always found accompanied by a reduction in the size of the thyroid gland. Criminis,³ however, records a case in Thibet, in which the gland was enlarged. In the Clinical Society's report, in 59 cases of myxedema noted, 4 showed enlargement of the gland, and in 3 of 22 of the total number of cases, the gland had previously been enlarged. It is very probable that, in these cases of enlargement, without exophthalmus, we have to deal with a gland in the early or hyper-

health. Witness the fact that in some cases where goiter has been present from childhood, growth and the mental status have apparently not been interfered with, and the patient is, to all appearances, in perfectly normal health, but where the entire gland takes part in the process, the patient's health must suffer.

Having a change in the structure of the gland, we naturally get a change in the character, or quantity of the gland secretion, or both, and it is to this change that the symptoms of these allied conditions are due. Where the goitrous enlargement disappears under the use of thyroid extract or other preparation of this gland, it is very probable that, through the entrance of the active principle of the preparation—believed to be an organic iodine compound, discovered by Baumann and by him named thyroiodin—into the system, the deficit of this compound in the patient's economy is made up, an equilibrium is re-established, and the abnormal activity of the healthy portion of the gland ceasing, this decreases to the original size.

In view of these facts, I think we are justified in looking upon a spontaneous enlargement of the thyroid gland occurring in infancy or childhood, as being the precursor of more pronounced symptoms of myxedema, if allowed to go unheeded.

In this connection the following cases may prove of interest:

Case 1.—Sadie K., 8½ years. Both parents American. No tuberculous or specific disease on either side; maternal grandfather has a well-marked goiter which, he says, has been present as long as he can remember. (Patient first seen during the early part of January, 1897. Child presents a well-marked tumor over the anterior and antero-lateral aspects of the neck. Tumor first noticed two years ago, and has been growing slowly but steadily ever since. Tumor corresponds to the location of the thyroid gland, and measures, as nearly as can be determined, about 3½ inches horizontally, and about 2 inches vertically. (See Figs. 1 and 2.) The left side of the tumor (right of cut) gives a distinct sensation of fluctuation, presumably due to a cyst. The outline of the cystic portion shows the

single daily doses of three grains, after which its use was again interrupted. Within a month the gland began to enlarge again. The resumption of treatment was again followed by a prompt reduction in size. The same results occurred in each instance, upon interruption and resumption of treatment. At the present time, and for some months past, the patient has been receiving a single dose of ½ gr. every second day, and the gland and the general condition have remained normal.

Case 2.—Sylvester C., 11 years. Hungarian. Came under treatment during the summer of 1897, for a cough which had persisted for some months, accompanied at times by slight muco-purulent expectoration. Physical examination revealed signs of a mild tracheo-bronchitis. The thyroid gland was appreciably enlarged, although, owing to indistinctness of its outline, the exact measurements could not be obtained. On palpation, the enlargement was apparently uniform over the entire gland, and nowhere of a cystic nature. Inquiry revealed that the mother of the boy has had a goiter since childhood, but apparently enjoys good health. No family history of syphilis or tuberculosis obtainable, except that a paternal uncle died of phthisis. The tumor had first been noticed four years ago, and had grown slowly. No symptoms of mental change

Sadie K.

left lobe and the isthmus to be involved. Over the right lobe the outline is less distinct, and the sensation that of a solid growth.

No pulsation over the tumor; no dilatation of the superficial vessels; no pressure symptoms; no apparent thickening, or scaling, or abnormal dryness of the skin. Hair coarse and dry; no falling out of hair has been noticed. Patellar reflexes unimpaired; no giddiness or headaches. It has, however, been noticed that the child's memory is somewhat impaired, in that she is beginning to forget her childish rhymes and songs. She is also less inclined to play with other children than formerly.

She was at first put upon the saturated solution of potassium iodid, in drop doses, t. i. d. This was continued for three weeks, with the result that the tumor became distinctly more tense and hard, but no smaller. January 26 the iodid was stopped, and the patient put upon a reliable preparation of thyroid extract, in tablet form, in doses of three grains, once daily for three days; after this in the same dose, twice daily, and then, after the same length of time, this was increased to three times daily, at which dose it was continued. Within two weeks a marked diminution in the size of the tumor was perceptible, preceded by softening over its entire surface. By the middle of the following April the tumor had entirely disappeared, and the child was to all appearances normal. (See Figs. 3 and 4.) For some months the extract was continued in

Sadie K.

had been noticed. The use of thyroid extract was begun—in addition to a mild expectorant—in accordance with the plan outlined in Case 1, with the result that, after one week's treatment, the tumor had decidedly diminished in size. After three weeks the gland had returned to its normal size, and remained so until the case passed from under observation, some weeks later. This removal from treatment was reported to be due to the fact that the mother said that she had had a goiter from childhood without suffering, consequently she could see no reason for its treatment in the boy. The cough had disappeared entirely.

Case 3.—Mary McD., 14; Irish parentage. The child was brought for treatment August 2, 1897, because of habitual constipation, frequently accompanied by headache. Further questioning and examination, because of the typically myxedematous character of the skin of the face, elicited the following facts: History of the beginning of the condition is indefinite. The mouth and limbs twitch a good deal at times. Sleeps poorly; is dull and listless, sitting in an apathetic condition almost the entire time; does not care to play. Memory very poor. The child is of an affectionate disposition but rather timid. At times develops a destructive tendency, although this is not marked; this condition has, however, been more marked during the past year. At times complains of a pain in the cardiac region, and of shortness of breath. Speech is indistinct and

stuttering. Seems to grope for the words. Slight thyroid enlargement. The child began to menstruate when 9 years old, and this function continued quite regularly for two years. During the past three years, however, it has been entirely absent. Thickening and puffiness of the skin, especially of the trunk and face; teeth irregular and of Hutchinson type; slight anemia; hair dry and wiry. No especial loss of hair has been noticed, although the eyebrows and lashes are scant. Some drooping of lower eye-lids, and puffiness of the skin under the eyes. Slight internal strabismus, noticeable only at times. Heart-action rapid and somewhat feeble.

Since the change in the child's condition was first appreciated, it has been noticed that perspiration has lessened, until now it is practically absent, even in hot weather. At the beginning of the change she was in next to the highest class in the primary grade in one of our Public Schools. As the condition developed the child was gradually "put back" into lower classes until she was again in the lowest class. Her teachers then recommended her removal from school. The girl is the product of the third conception. The first terminated at the seventh, the second at the middle of the eighth month. In both instances the fetus was still-born. No direct history of specific disease in either parent is obtainable. Several other children in the family are apparently normal and healthy. Weight 68 lbs.

The diagnosis of myxedema accompanying congenital syphilis was made, and the treatment, as outlined in Case 1, begun.

September 15, a gradual improvement has been noticed since the beginning of treatment. Child acts brighter; wants to go out and play. First change noticed was that the child, of her own volition, seized a broom and swept the room. Now desires to help her mother with work, such as drying and washing dishes. Speaks far more plainly. Begins to spell and write again. September 22, at the end of the first week of treatment weighed 65½ lbs; now weighs 70 lbs. She again takes up her slate and has begun to play with her doll. Recalls some facts about her class and teacher. November 1, much brighter; wants to go to school; sleeps quietly at night now. Has begun to read in the "first reader." Has become sensitive to the taunts of her playmates. Not much lessening as yet in the thickening of the skin. Since the above the child has been kept steadily under observation and treatment. The mental condition has slowly but steadily improved. While still far from being a bright child, she is, compared with her former mental state, a different being. The general physical condition, too, is much improved, although there is still much thickening of the skin. The thyroid enlargement disappeared within the first month of treatment.

The only unpleasant effect of the extract noticed in any of the cases, was restlessness during sleep in Case 1, after the treatment had been in progress several weeks. Cessation in the use of the extract for a few days was quickly followed by the complete disappearance of the symptom.

I have chosen to class the above three cases together as variations in degree of the one condition, myxedema, for I believe that in those cases of goiter in which thyroid extract exerts a beneficial effect, by causing the disappearance of the enlargement, we have to deal with a condition of the gland, which may, if unchecked, go on to the development of a more pronounced form of this disease, as we see it in the adult, or of the cretinoid state, according to the age of the patient. Furthermore, I hold a trial of the thyroid extract, in cases of goiter without exophthalmos in children, to be fully justified. Bruns⁵, of Tübingen, in speaking of the treatment of twelve cases of goiter gave as the result: Four children (ages 4 to 12), were cured completely. At the end of a fortnight there was a marked decrease observable in the size of the tumor, and in one month thereafter it had entirely disappeared. In one case of goiter, accompanied by a cyst in the thyroid, the goiter disappeared, but the cyst remained unaffected by the treatment. He gave one to two drams of the fresh thyroid gland inclosed in a wafer, or in a sandwich, once a week. His conclusion was that the treatment succeeds best in children. Herrick⁶ states that thyroid extract is of value

in simple hyperplastic struma, especially in the young.

I am indebted to Prof. A. Jacobi and to Dr. F. Huber, his chief of clinic, for the privilege of reporting Cases 2 and 3.

NEURAL DYNAMICS.

Presented to the Section on Neurology and Medical Jurisprudence, at the Forty-ninth Annual Meeting of the American Medical Association, held at Denver, Colo., June 7-10, 1898.

BY W. J. HERDMAN, M.D., LL.D.

ANN ARBOR, MICH.

The learned author of our most recent work on the nervous system and its diseases has said: "Some knowledge of the dynamics of the nervous tissues is of fundamental importance to the student of nervous phenomena and nervous disease, who should know something of the stimuli to which nerve-cells and nerve fibers react; of the manner and degree of this reaction; of the phenomena by which it is attended and of the nature of molecular transmission." (Chas. K. Mills.)

Progress in clearing up the mysteries which attend especially the origin of functional disorders of the nervous system requires more complete and exact knowledge of neural dynamics. And as the organic changes are but the secondary stages of disorders which were necessarily functional in the beginning of the derangement, faulty dynamics must account for these also.

In the nervous system, exhibiting vital phenomena either of normal or abnormal nature, we have to deal with matter and motion: the same two elements which underlie all the phenomena of the physical universe. Right conceptions therefore of the nature and arrangement of the matter which constitutes nervous tissue and of the motions which act upon it and originate in it are indispensable to a correct interpretation of nerve action. Our knowledge is changing and enlarging daily concerning the structure and arrangement of the nervous tissues which constitute the machinery that serves to receive, transform and transmit the motion peculiar to it, and this added knowledge requires us to modify the conceptions we have previously entertained of the workings of that mechanism. It is but natural that the recent positive acquisitions to our knowledge of the minute structure of the nervous system have stimulated endeavors to explain by means of them many of the phenomena, both physiologic and pathologic, which are associated with nerve action, such as sleep, hypnotism, hysteria, epilepsy, etc., which have baffled all attempts at explanation and yet have for many reasons provoked perpetual inquiry. But it has seemed to me that all attempts at explanation that have come under my notice, even though they have called to their aid the evidences furnished by modern histologic research, have been too narrow in their conception and too limited in the range of elements considered as entering into the processes dealt with, to be of much profit in elucidating them. I refer especially to such suggestions made by several biologists and some neurologists as the one that the phenomena of mental action, hysteria, hypnotism, sleep, etc., may be accounted for by the mobility of the dendrites of the cortex neurons. Even if we should

ultimately discover it to be a fact that the neuron prolongations possess such mobility—for this at present is little more than an assumption—the questions still remain to be answered: What occasions such movements? And how do they serve to transmit impressions from neuron to neuron? We must have firmer ground to rest on than that furnished by a doubtful ameboid movement of neural protoplasm before we can form a very rational or comprehensive conception of the dynamics of the nervous system.

Starting with the essential elements by means of which nerve phenomena are manifested, we find them consisting of three main sets of neurons: 1, The afferent (or sensory); 2, the central; 3, the motor or efferent. These constitute the machinery for transforming various forms of what might be termed extraneural energy into neural energy and again delivering it in some form to the outer world. In considering neural dynamics therefore, we have to occupy ourselves with the nature of this machinery, the neurons, and with the various forms of energy which it serves to transform.

We find the neurons discontinuous cell-elements best arranged for their effective work in chains, each link so related to its special associates as to, in some manner, influence them and not others. These cell-elements are composed of a vitalized protoplasm of highly complex chemic composition in which conditions are most favorable for a great range of molecular rearrangement and modification. The character of the arrangement and modification of the protoplasmic atoms and molecules will of course be determined by the nature of the motions to which they are subjected, and whereas, we can conceive a congregation of living protoplasmic molecules may offer at first some resistance to any extraneous form of motion by reason of their pre-existing inter-chemic and inter-molecular relations, yet any added motion from external sources to which they are able to respond would in time, by its frequent repetition, result in modifying their structure and arrangement. While we may not be able, as yet, either by chemic analysis or by microscopic research to distinguish any difference in the composition or structure of the protoplasm that makes up the substance of neurons differing in function, yet it is presumable that such a difference does exist, and is evidenced by their special capacity to respond to certain forms of motion and not to others. This assumption of the difference in molecular arrangement of the protoplasm of neural chains of different function, is still further justified by the very evident structural difference in the end-organs of the neurons where they first receive that form of motion to which they are especially sensitive and which constitutes their peculiar stimulus.

The human organism possesses six distinct forms of peripheral expansions of sensory neurons: olfactory, optic, auditory, gustatory, tactile, muscular, all of which can be readily demonstrated, and it is highly probably that sensations of temperature and the various forms of common sensation (such as that of position, pain, hunger, thirst, fatigue) have a special terminal nerve structure capable of responding to the conditions which attend each of them. It is chiefly by means of these special mechanisms constituting the end-organs of the sensory nerves that the human organism is capable of utilizing the various forms of energy which it receives and in turn transforms them into the neural and other activities characteristic of

animal life. Energy in the form of translatory motion of comparatively slow and perhaps irregular periods is transformed into nerve motion by the tactile corpuscles and the nerve terminations in muscle spindles. More rapid translatory motion with shorter wave lengths excites the mechanism which ultimately reaches the special end-organ of the auditory nerve.

The sense of touch and the muscular sense are excited by direct pressure of an object on the end-organ, or by the communication of such pressure through the medium of the overlying skin or other tissues. In the sense of hearing the end-organ of the auditory nerve requires that the pressure be communicated through the medium of the elastic atmosphere, which, while it is motion of much greater frequency of pulsations of periods (16,000 per second being the ordinary limit of sound perceptions for the human ear), is still a form of motion that may be termed molar in distinction from molecular motion. The end-organ of those neurons that are designed to detect varying degrees of temperature are tuned to molecular motion in which the wave lengths and the frequency of vibrations far exceed those which excite the auditory sense. Radiant energy, which in its slowest molecular vibrations we recognize by the temperature sense as heat, consists of vibrations in the ether of at least 107,000,000,000,000 per second, and as the highest audible note that can be detected by the best trained human ear is produced by about 40,000 impulses per second, there remain over thirty-one octaves of vibrations which, in all probability, exist in the universe either in the air or in the ether, for which the human organism possesses no receptive mechanism by which consciousness can be impressed, since we have no sensory nerves adapted for responding to such vibrations as intervene between the highest sound vibrations that the human ear can detect and the slowest ones that are recognizable as heat.

The ether vibrations known to us have a frequency varying from 107,000,000,000,000 per second to 40,000,000,000,000 per second, a range which if expressed in musical terms would amount to about 8½ octaves. All of these ether waves are capable of transformation into heat or chemic action, according to the nature of the substance upon which they fall. The slower waves are, however, better adapted for transformation into heat, the more rapid ones for effecting chemic interchange. Certain of these ether waves, those with a rapidity of vibration from 293,000,000,000,000 to 757,000,000,000,000 per second "not only produce thermal and chemic effects, but have the power when they strike the retina of the eye of causing changes in the layer of rods and cones, which in their turn act as a stimulus to the optic nerve." The primary stimulus is here, as in the touch, muscular, auditory and temperature sense end-organs, a wave of motion communicated from an external source either by direct contact or through the medium of the air or the ether. If the rods and cones be wanting, as when the structure of the retina atrophies, ether waves, within the specified range for the normal retina, may beat upon the wasted surface continuously but without avail in exciting light sensations. The peculiar structural or molecular arrangement which is present in the normally acting rods and cones of the retina is indispensable for the production of visual sensations, as likewise are ether waves of the proper rapidity.

While we do not know positively the nature of the change which takes place in any one of the forms of

sensory end-organ so far considered, when acted upon by its appropriate kind of motion, analogies in physics and mechanics teach us that the end-organ is simply a machine devised for transforming that special form of motion into another form of motion that we term nerve-motion. The majority of the facts, which we have not now time to enumerate, appear to justify the conclusion that the first step in this transforming process is a chemic change, a rearrangement in the protoplasmic molecules of which the cells in the end-organs are made up.

In the two remaining special senses—smell and taste—where the substance affecting the end-organ first enters into solution and is thus brought into intimate molecular contact with the cells forming the end-organ of the sensory nerve, the chemic nature of the primary step in the stimulation seems to be without question. Since atoms of substances known to us make up the protoplasmic molecules of these end-organs, and since motion in forms with which we are also somewhat familiar, are the primary agents of stimulation or excitation of these molecules, we are justified in attempting an explanation of what occurs by the use of these terms already familiar to us before assuming the intervention of any new or less familiar ones. We know that these various forms of motion do cause molecular rearrangement, that is, chemic modifications, in the complex organization of living protoplasm. Unstable protoplasmic compounds in the end-organs are shaken into an arrangement of molecules more stable, and the molecular or chemic rearrangement results in the setting free of a certain amount of energy in some form, to become potential or be expended elsewhere. What occurs as a result of this is a modification of some sort, in the peripheral neuron with which the end-organ is connected; a modification that enables it, in turn, to change the conditions present in more central neurons with which its ramifications are associated. Whenever the energy set free in a peripheral sensory neuron gives rise to changes in an associated central neuron that energy has taken the form of some sort of motion.

In the light of our present conception of the histologic composition of the nervous system, that of associated but disconnected individual elements, what is the form of motion that will best account for this influence which we see exerted by one neuron upon another? In attempting to answer this question we must remember that "chemic action implies electric action, electric action implies conduction and induction, distribution and attraction, resulting in movements which may be massive, molecular or atomic, and these movements result in selective groupings." (A. E. Dolbear.) It is possible that the resulting movements due to chemic changes and their accompanying electric action, which takes place in a neuron as the result of stimulus, may have at times a range sufficient to be detected under the microscope, provided the conditions are favorable, and so give foundation to the belief in ameboid movements of nerve-cells, but this is merely incidental. It is certainly true, and can be demonstrated, that the molecular disturbance within the protoplasmic contents of a living cell does cause a change in the surface tension of the cell, and this is accompanied by a difference in electric potential which is also demonstrable. Not only at the moment of stimulation would the living neuron possess this condition of surface tension and electric potential of static form, but this would be its normal condition at all times, as a result of the nutri-

tive activities in the protoplasmic contents. At the moment of appropriate stimulation the electric potential would be in some degree changed—either increased or diminished—and the relations which neurons bear to each other in associated chains is such that a variation in the electric potential in one would be attended by a corresponding change in the others. Some such view of neural dynamics appears to be held by Broadbent, who in a recent address on "Brain Origin" (*Brain*, 1895), after reviewing certain of the current theories, has said, "It has long seemed to me that a conception which better fits in with all the phenomena of nervous action is, that instead of this passive attitude of the periphery and centers one to the other, and of the centers, sensory and motor alike, toward each other, the relation in all cases is one of mutual tension and resistance. That is, that at all points specialized for the liberation of nerve motion, latent energy is generated and exists in a potential form, which in the absence of restraining condition is a counterbalancing energy developed in the centers or peripheral nerve expansion, with which any given point is connected by nerve fibers."

My conception, suggested by the structure and arrangement of neurons, and one which appears to be justified by the facts as far as we know them is, that associated neurons bear the relationship to each other of charged electric condensers. A disturbance of potential in one can not take place without causing a correlated change in the associated ones. This implies that the substance separating the associated neurons is of the nature of an insulator or non-conductor. That a substance differing in structure and function from that of the neurons does lie between them, and that this substance does not interfere with the action of one neuron upon its associated neurons are facts which we must recognize. "In physics, proper, whenever there is a lack of continuity in the medium where energy is being transferred, there is a corresponding change in the form of the energy." (Dolbear.) Whatever the nature of the energy that is developed in the neuron, it must undergo some modification in order to cross the interneural substance. If a state of static tension in the neuron is created by the nutritive activities that are continually maintained within it—and of this there can be no doubt—then accompanying this static tension there will be set up in the environment of each neuron an inductive influence which, in a state of rest, will be exactly balanced by the opposing inductive influence emanating from associated neurons. But where action takes place, as when the peripheral sensory neuron is disturbed in its molecular arrangement, and so in its static potential, by some impinging motion acting as a stimulant to it, then the inductive influence surrounding the disturbed neuron, and which envelops or extends into the field of its associated neurons, is correspondingly modified, and this modification in induction in turn acts as a stimulus to the central associated neurons. It appears to me that the change which the energy undergoes in effecting its passage from neuron to neuron is of the nature of magnetic induction resulting from a change of static tension. Chemic action, heat, pressure or mechanic movement, none of them seem so well adapted to effect the definite and prompt reaction that follows the disturbance due to a stimulus, as does energy in this form of static electric tension.

My attempt has been to propose a theory which will not only account for the generation of what has been

termed nerve force, but which will also account for its conduction in the neuron, and its transmission from neuron to neuron. To do this I have sought to reduce to their simplest conceptions the physical and physiologic conditions present in the structure of the essential elements of the nervous system, and to state what appears to me to be the most probable physical results of such conditions consistent with the phenomena we observe. In recapitulation: The nutritive processes of the neuron, presided over by the nucleus, maintain the protoplasmic contents in that state of readiness for action which constitutes the primary or fundamental stage of all nerve function. This creates in the neuron a condition of surface tension and of static electric potential, and is perhaps accompanied by some protoplasmic or ameboid movement.

Each neuron in this state or condition has a restraining or balancing influence while at rest, upon all other neurons within its field of influence by reason of the energy exerted by it in the form of what is known as electro-magnetic induction.

The end-organs of the sensory nerves serve as avenues of ingress for such forms of motion as are attuned to their mechanism, and this added motion serves to create a molecular rearrangement of the nature of a chemic change in the protoplasm of the neuron, and this is accompanied by a change in the static potential.

A change in the static potential is inseparable from a change in the electro-magnetic field surrounding the neuron, and this variation of the electro-magnetic field acts as a stimulus upon every neuron associated with the one whose end-organ has been excited.

Thus conduction and transference of nerve force are, according to this theory, to be regarded as of the nature of electro-static phenomena.

DISCUSSION.

Dr. COE of Oregon—As I came in a friend of mine in another Section wanted to know where the Section on Neurology was to hold its meetings. I told him in the Baptist church. He said, "I think if there is any Section that ought to meet in the Baptist church it is the Neurological Section, because if any one gets into deep water it is the neurologists;" and I think that this is entirely too deep for me to discuss at this time.

Dr. D. R. BROWER of Chicago—I am not equal to the discussion of this important question. Some of the statements in the paper are facts, and these we all admit. As to the theories therein, they are plausible and reasonable theories, and I thank Dr. Herdman for the wonderful suggestiveness of his paper.

Dr. SEARCY—I have been much interested in the paper on the dynamics of the nervous system. It is one of the opening fields of medicine, and psychologic medicine especially. The unit of life is the cell, and the unit of the nervous system is the nerve cell. We are learning probably more of the action of the nerve-cell in the neuron of the cortex than in any other part of the nervous system, because we find those cells more isolated and more easy of access in their structure, their function and their site. As worked out of late, possibly we can say the dynamics of the neuron consist of the received motions, and adjusting its emitted motion to those received—which is a vital phenomena. The way I have criticized nearly all philosophic theories along this line is that we attempt to describe animate phenomena by inanimate phenomena; for instance, describing the functions of the neuron by a reference to electricity. We would simplify our work if we would describe vital motion by simpler vital motion, describing, for instance, the extremely complex nervous system of man by studying the movements in the lower organisms, in ameboids and protozoa, showing the movements in their simpler forms. We can grade up the vital phenomena from that basis much better than we can by attempting to explain them by inanimate phenomena.

Dr. ADAM A. FORD of Denver—One suggestion came to me in listening to this very able paper, and that is with regard to the ultimate action of the molecule, or rather the atom in the molecule, affecting the neuron extremity. The paper indicated

a variety of different actions due to vibratory action up to a number of trillions. Where can we differentiate chemic action from other action? Can we not trace it to the various forms of vorticular action in the action of these ultimate atoms? I believe it is one of the theories of scientists, now accepted; that this co-ordinated form of action in the atom is vorticular action, and owing to the different formation of this vortex, together with its affinities, we have certain manifestations of power, of force. Might not the author of this paper explain this theory, so as to include vorticular action?

Dr. MEYER—I should like to ask Dr. Herdman with regard to the conduction time. The conduction time has been used in a great many of the du Beromo phenomena in nerve elements. It seems, if I may trust my memory of physics, that the difficulty of meeting the objections rising from the conduction time become rather greater in the theory suggested, than even in the idea that was originally held by du Beromo.

Dr. PETERSON of New York—The author has given a great deal of thought to this subject, and the critic of his paper should at least give as much time as he has to it. The paper is purely speculative, but speculative papers, I think, always have a certain charm. The theory advanced, in my opinion, is as reasonable a theory as ever given in neural dynamics. If I understood Dr. Herdman rightly, it was based upon the installation and independence of the neuron. That is by no means proved, and the most recent researches would tend to show that it is probably untrue. However, theories like these are the tentacles of the scientific octopus, reaching out in every direction for truths, and therefore, are extremely useful.

Dr. W. J. HERDMAN—While, as has been said, such papers as this are largely speculative, my attempt has been to give a solid foundation of fact for the building up of those speculative ideas. The question of vitality has been raised. It is, as we all know, a very much debated question among physiologists at the present time as to whether all manifestations of vitality are not physical and chemic; that molecular arrangements have simply reached a certain stage when these are the natural outcome of the molecular and anatomic arrangement; and I must say that, from the recent investigations I have made on that subject, covering the last five years, the evidence is largely on the side of the man who holds what is called the mechanic view. It is with relation to that view, and to making it bear on the side of neural dynamics, that this paper has been prepared. I have not yet subjected the theory to the tests of nerve condition, as has been asked by Dr. Meyer. I have not conceived how it could be, or how the static condition of an individual neuron could be subjected to the test which has been made of nerve conductivity in the physiologic laboratory method, but some device, perhaps, can be arranged for bringing that under observation as well. It has seemed to me that we must take into consideration what we know in physics and physiology, and bring this knowledge together, and see how the two will dovetail.

UREMIC FOCAL LESIONS.

Presented to the Section on Neurology and Medical Jurisprudence, at the Forty-ninth Annual Meeting of the American Medical Association, held at Denver, Colo., June 7-10, 1898.

BY H. H. HOPPE, M.D.

Lecturer on Nervous Diseases, University of Cincinnati Medical Department; Neurologist to Cincinnati Hospital.

CINCINNATI, OHIO.

The literature on localized lesions of the central nervous system occurring as a result of uremic attacks is very scanty. A diligent perusal of many American text-books on general internal medicine, as well as the text-books on nervous diseases, fails to find mention of the subject at all.

It is true that compared with the multiform manifestations of uremia, especially compared with the frequency of convulsive attacks, the paralytic attacks occur very rarely; or, perhaps, it were better to say, are rarely recorded, and this is probably due to the peculiar character of the paralytic attacks and to the rapidity with which the manifestations disappear. The study becomes all the more interesting because of the light which the subject seems to throw upon the nature of other central disturbances of the nervous system. If the advance in our knowledge of medicine has been marked in the past quarter of a

century in any one particular direction, it is in that of the somatic origin of the various forms of insanity and of the ordinary diseases of the nervous system, in other words, that the intellect or the soul itself is never affected, but that its disordered manifestations are due to a diseased condition of the media through which it acts. The first successes, among which we may mention Mendel's classic demonstration of the pathologic conditions underlying dementia paralytica, were followed by countless endeavors in all parts of the world to establish the relation between diseased conditions of the brain and the disordered manifestations of cerebral activity. The results, as regards cerebral localization and mapping out of areas of the cortex, with their distinct functions, both sensorial and motor, have, as you know, been crowned with brilliant success. It, however, had a tendency to narrowing our conception of nervous diseases, by referring, or trying to refer, all disordered conditions of the nervous system, psychical, sensorial and motor, primarily to the brain or spinal cord. We know today that the anatomic investigation of the majority of insanities and of all the so-called functional diseases of the nervous system has met only with signal failure.

It may be held that this failure is due to the inefficiency of our physical and chemic means of investigation, but the probabilities are that we will have to go back to the old clinical methods of investigation: to study the human body in life as well as the organs after death. To look upon sickness, no matter what its character, may be a manifestation of a disordered condition of the whole body rather than a disorder of the function of one particular organ. In the light of recent investigations, especially of the functional diseases, we know that the brain and spinal cord are often more sinned against than sinning, and that a remedy for the relief of the functional affections is more often to be sought in correcting a disordered condition of blood, stomach, intestines, thyroid gland and kidneys, rather than of the brain. Bouchard, in his well-known publications on auto-intoxication, started the pendulum to swing away from anatomic investigations of the brain in functional diseases to the study of diseased manifestations of the more distant organs of the body. More beautiful and more classic disturbances of the functions of the central nervous system can not be found than the investigation of the nervous arrangements found in uremic intoxications.

I have purposely waited a very long time before publishing these cases, because I wished to be sure of the diagnosis. We know only too well how our most interesting and rare cases are cleared up and relegated to the classes of common diseases by time, which as a rule, shows us that that which we looked upon as a rare or extraordinary occurrence or disease was only an ordinary symptom out of time and place.

Case 1.—Uremia in which the first symptom was aphasia, which continued half an hour, followed by a convulsion and hemiplegia of the right side, with complete recovery in twenty-four hours. Mrs. C. K.—, aged 62, married, mother of five children. No miscarriages, no history of syphilis. Patient, who is very heavy, had never been sick before. At noon, Nov. 12, 1895, while at dinner, in the best of spirits, and with a good appetite, she suddenly quit eating in the midst of her meal, attempted to speak, then muttered some unintelligible syllables, grew very much excited on account of her inability to speak, arose from the table and walked about the room. On account of her unintelligible jargon the family thought that she was delirious and had suddenly become insane. She could

not make herself understood, was unable to answer the excited questions put to her, and on my arrival, about half an hour later, was much excited, tried to speak, but could not form her words. She stated afterward that she knew perfectly well what she wanted to say, but could not express her ideas in words. Her face was flushed and congested, the pulse full, hard and rapid. No vertigo, no vomiting, no difficulty of breathing. I obtained a specimen of her urine, and after ordering a purgative by mouth and enema, put patient to bed. On returning after about an hour, after making an urinalysis, I found her unconscious and in a violent convulsion. The convulsive movement, however, was limited to the right side. Respiration stertorous, face deeply congested, the left side flabby and relaxed, the right in a state of clonic convulsions, the left arm and leg were perfectly flaccid and relaxed. After cessation of consciousness the right arm and leg were completely paralyzed. A hot bath was given; profuse perspiration ensued on use of pilocarpin, diuretics and saline purgative. In about an hour consciousness returned, but patient was unable to speak. The paralysis of arm, face and leg was complete on awakening. About 6 P.M. patient began to talk, but not perfectly, still enough to make herself understood. In the course of the next few hours slight movement returned, and in twenty-four hours speech, as well as use of arms and legs, was again perfect. In two or three days the patient was able to be about. Was placed on a strict diet and treated with alkalines, baths and cathartics. The quantity of albumin gradually diminished, but never disappeared entirely. After eighteen months patient is still well; no recurrence of uremia or paralysis. Albuminuria still present; quantity very slight. One interesting point about this case is the double focal lesion—the left third frontal convolution and the right psychomotor area.

Case 2.—June 15, 1896, Mr. H., aged 61, married. Parents both died at an advanced age, presumably from bronchopneumonia. Has not been sick from childhood. Has been a hard worker all his life, doing the work of a molder. While eating dinner, just at the commencement of the meal, patient suddenly lost consciousness, his head sank on his breast and he fell forward, slipping out of his chair on to the floor. He was immediately picked up, and regaining consciousness in a few moments, was supported to the next room and laid on a bed. The family noticed that his face was drawn to the left side, and that he made no use of the right arm or leg. There were no twitchings or convulsions of any kind. I arrived on the scene a half hour after the onset of the attack. Examination: Patient is still in a semi unconscious condition; can be aroused, however, and is able to assist at the examination. Pupils are normal in size and respond to light, both sides are equal, ext. muscles of both eyes are normal in their function. The right side of face has lost its expression, the naso-labial fold is absent on opening the mouth. The left angle is drawn upward. The tongue is protruded to the left. No loss of sensation in region supplied by fifth nerve. The right arm can scarcely be moved; there is not a complete loss of muscular power, but the grasp of the hand makes scarcely a perceptible impression. The movement of the right leg is good, but there is scarcely any motor power. Reflex of right leg very much diminished. No loss of sensation of either arm or leg. The examination of urine revealed the presence of albumin. Purgation and sweating. On my return, in three hours, I was surprised to see the muscular power of the leg normal; that of the arm greatly increased. On the following morning the paralysis had entirely disappeared.

Albumin remained in urine for about four months. Patient was treated by alkalines and a non-nitrogenous diet. For past eighteen months the urine has contained no albumin at all, and the patient considers himself entirely well.

Case 3.—This case shows one of those variations of focal lesions in which the paralytic onset occurred independent of an attack of uremic convulsions. It is true that the diagnosis is somewhat in doubt. The apoplectic attack may have been caused by an embolism or a hemorrhage from a small artery in the neighborhood of the internal capsule. In my opinion, however, the paralysis was, at first, so complete and the recovery from it so rapid and complete that I have no doubt but it belongs to the category of uremic hemiplegias. J. P., Grand Rapids, Mich., aged 55, unmarried. No history of nervous trouble in the family. Has never been sick, nor nervous. Dec. 5, 1897, at 9:30 P.M., patient, while playing cards, suddenly noticed that he could not use the right arm. A few moments later, while standing on the floor, he sank and would have fallen had he not clutched the table with left hand. The face became distorted at the same time, by the loss of use of right side. No diminution or loss of consciousness; no loss of speech. Patient was taken home at once in a cab. Physician

called and diagnosed right sided hemiplegia, with involvement of face. Urinalysis showed presence of large quantity of albumin. The attack was sudden, preceded only by violent frontal headaches of some weeks' duration. Regained use of arm in a few hours, and in twelve hours the recovery was complete. Use of leg regained in twenty-four hours. Six weeks after attack patient came to Cincinnati. The examination of nervous system was entirely negative. The examination of the urine showed the presence of 2 per cent. of albumin, large numbers of hyaline and granular casts. The case has been under treatment for Bright's disease for four months at the Good Samaritan Hospital. No uremic symptoms have shown themselves in this time. Quantity of albumin and number of casts remain the same.

Case 4.—The following case seems to bear out the theory that some local predisposition is necessary for the development of the paralytic attacks, some cause present in the center or area of the cortex which renders this center more liable to be attacked by the poisons circulating in the blood during an uremic attack rather than the other parts of the surface.

Mrs. F., aged 64, married, mother of seven children, all healthy, slightly nervous in temperament. Has never been sick before the development of Bright's disease some years ago. Was treated for arteriosclerosis and fatty degeneration of the heart for past three or four years. I saw patient first in January, 1896. Will not burden you with the text of examination except to tell you that she presented a typical fatty heart with well-marked arteriosclerosis. The urine on examination, dark in color, s.g. 1014, 2 per cent. of albumin, no sugar. In August, 1897, patient had a sudden attack of apoplexy, involving external recti of both eyes, especially of the right eye. The right side of face and tongue were involved. Complete loss of power in right arm and right leg, partial paresis of left leg.

Diagnosis: Acute bulbar paralysis, due to thrombosis of a branch of basilar artery in the upper part of pons. Patient gradually improved, and after three or four weeks was able to walk about, although with much difficulty. The arm recovered completely, the right side of face and tongue, as well as the right external rectus, have not recovered after a lapse of two years. On Feb. 12, 1898, was called to see patient. The attendant nurse stated that she had not been as well as usual for a few days; that she had had attacks of vertigo and felt sick at stomach; that she had been somnolent all morning and had not been able to move the right arm and leg at all.

Examination: Patient is in a stupor and can not be aroused sufficiently to assist in the examination. The pupils are contracted and equal in size. Unable to examine external muscles of eyes on account of coma. Constant twitching in the left side of face, loss of sensation of left side of face. The left arm and left leg are in a constant state of clonic spasm, the spasms are small in excursion and momentary in duration, following each other very rapidly. These spasmodic attacks have recurred three or four times in the course of two hours, an interval of fifteen minutes probably between each attack. During the interval the left arm and leg are seen to be completely paralyzed. The muscles are flaccid, relaxed, the limbs fall by their own weight without any resistance on part of the muscles; patellar reflex absent; sensation can not be examined into on account of presence of coma; right arm and leg normal.

Treatment: Purgatives; profuse perspiration induced by heat, applied by using hot water in rubber bags. Consciousness returned in about an hour. The diagnosis of left-sided hemiplegia confirmed by patient's inability to use the arm or leg. The paralysis of the arm and leg disappeared in four or five hours. On the next day the patient was in her usual condition. April 16, 1898, patient again had an attack of uremic coma, with left-sided hemiplegia, and again recovered as in previous attack.

A CLINICAL STUDY OF UREMIC PARALYSIS.

The four above-mentioned cases represent, with but slight exceptions, the clinical aspect of uremic paralysis, and we may draw up in a concise manner the clinical picture of this trouble.

The prodromal symptoms.—While the uremic focal disturbances seldom occur without premonition, we can hardly claim that it has any premonitory symptoms of its own. The onset of the attack is sudden, being either the ordinary uremic convulsion or a sudden attack of aphasia, Jacksonian epilepsy or paralysis, with or without convulsions or loss of consciousness. The premonitory symptoms are rather those of Bright's disease, uremic manifestations of a disor-

dered function of other organs of the body, or there may be general cerebral disturbances, such as headache, vomiting and vertigo, or localized edemata, which are manifestations of a general uremic condition. The uremic attack as such may be typical in its character or it may not be.

During an attack of uremic convulsions with loss of consciousness, heavy stertorous respiration, a full, bounding pulse and contracted pupils, the convulsions may suddenly cease on one side and continue on the other, the limbs in which the convulsions have ceased become flaccid, the muscles become relaxed and when lifted up and allowed to fall, drop in the direction that the force of gravity dictates, muscles offering no resistance whatever to the falling of the limb. The tendon reflexes are usually absent; there is very often a complete loss of sensation in the affected limbs. The face often becomes distorted by the convulsions of the muscles opposite to the paralyzed side, the mouth becomes drawn over to the side free from paralysis, while the cheek on the paralytic side becomes distended by each expiration. Boinet lays down the rule that the uremic hemiplegia coincides always with the uremic coma, and that it disappears when the coma disappears. While this is the rule, we know from the study of reported cases that there are very frequent deviations from it. In the typical cases, it is suddenly noticed during the progress of uremic convulsions that one side of the body is stricken with paralysis in the manner above described. This hemiplegic attack continues during the entire uremic convulsion, and if the outcome is fatal the paralysis is present up to the time of death. If the uremic attack yields to treatment, the hemiplegia sometimes disappears as soon as a patient regains consciousness. In other cases the paralysis rapidly diminishes and in a few hours the muscular power is completely restored. Dr. Rose of Berlin states that these attacks can occur like ordinary apoplectic attacks; after a good night's rest the individual awakens in the morning to find himself paralyzed. Only in very rare instances does the hemiplegia last longer than twenty-four or forty-eight hours.

In rare instances, as Case 3 illustrates, the hemiplegia may begin and become complete while the patient is in full possession of his senses, and the attack is not followed by coma. Case 2 illustrates a mode of onset also rare, in that the coma and hemiplegia occurred simultaneously without being followed or preceded by uremic convulsions. The paralysis has all the characteristics of being cortical in origin. In the beginning, perhaps but for a few minutes, it is complete, but rapidly gives way to paresis. The chief characteristics of the hemiplegic attack are the flaccidity of the muscles and the rapidity with which the paralysis disappears. Boinet states that another of its characteristics is its variability. It is complete in the morning, diminishes at night and increases again in intensity a few hours later. Lancereaux reports a case in which the hemiplegia occurred first on one side of the body, disappeared, and then occurred on the other side. Case 1 is similar to this, aphasia occurring first in a right-handed woman, and during the uremic convulsion which follows there is developed a left-sided hemiplegia.

It is probable that cases where the paralysis was of long duration and those that were followed by contractures were due to localized hemorrhages in the cortex.

The paralysis of the facial muscles may or may not be present in these uremic hemiplegias, and when it is affected it follows the laws of cortical facial paralysis, namely, the lower half of the face alone is involved. Raymond reports a case attended with ptosis. Passing amaurosis is common. Bernard, Chauffard, Raymond, Chantemesse and Level report cases in which the hemiplegia was associated with conjugate deviation of the head and eyes. Aphasia occurring with right-sided hemiplegia is quite common, but occurring alone, or as in Case 1, occurring in a right-handed person with left-sided hemiplegia is very rare. In all four cases which I have recorded, at the time of the examination there was an absence of the loss of sensation. Boinet, however, states that there is habitual association and hemianesthesia with the hemiplegia, and that this hemianesthesia has all the characteristics of being cortical in origin. It is always incomplete and exceedingly transitory, often disappearing before the disappearance of the paralysis. Raymond reports one case in which the anesthesia affected the entire body, another in which the conjunctiva and the mucous membranes were anesthetic.

It is possible that at times also the anesthesia may affect the special senses, as Boinet's case, where the sense of hearing was lost for three weeks.

The prognosis as a rule is bad; the majority of the cases reported were fatal.

The hemiplegic attack itself does not offer a bad prognosis. The prognosis depends upon the severity of the uremic attack, and in my opinion the presence or absence of hemiplegia does not have any influence on the prognosis of the attack, the hemiplegia disappears simultaneously with it or it rarely lasts longer than twenty-four hours. The second of the cases reported in this paper is completely cured, the hemiplegia and the kidney trouble having completely disappeared. I do not believe, however, that there is any relation between the intensity of the renal disturbance and the cerebral symptoms, in this sense, that the most severe forms of uremic convulsions are apt to be followed by cerebral symptoms due to some inherent localized weakness in the cortex of the brain. It seems that the cases that are associated with high temperatures are apt to be fatal. Conjugate deviations of the head and eyes are also unfavorable symptoms.

The diagnosis is very easy, if the examination is carefully made. While it is true that ordinary apoplectic attacks caused by hemorrhage in the brain or by embolism in the cerebral arteries may be accompanied with epileptiform convulsions, an examination of the urine will clear up the diagnosis by demonstrating the presence of large quantities of albumin in the urine. We must not forget, however, that patients with Bright's disease, especially those with interstitial nephritis have as a rule arterial sclerosis and may have an attack of hemorrhage into the brain during the uremic convulsions, which may give rise to hemiplegia during the comatose state. The variability and the flaccidity of the paralysis, the normal temperature and the rapidity with which the paralysis disappears, will enable us to make the differential diagnosis. It will not be so easy, however, to differentiate the purely functional cases of hemiplegia from those due to minute hemorrhages into the cortex (Senator).

A very interesting feature of uremic focal manifestation is the occurrence of localized Jacksonian epi-

leptic attacks. When we take into consideration, as we shall see later, the entire absence of any organic change in the cortex, this feature becomes all the more interesting, because of the almost universal association of an organic focal cortical lesion with the occurrence of circumscribed epileptic attack. Chantemesse and Tenneson, Chauffard and others have reported cases of this kind with autopsies, Dunin five clinical cases, Boinet one. In some of the reported cases the epileptic convulsions occurred during an uremic attack and in others preceded such an event or occurred entirely independent of a generalized intoxication. In Boinet's case four distinct and separate attacks occurred without the attack being followed by paresis. After the fifth attack, however, the hemiplegia set in. The above cited cases, and there are still more in literature, are pure cases of Jacksonian epilepsy. Case 3 in the present report presents a localized epileptiform seizure, but convulsions were present in the paretic extremities.

CAUSATION.

The real cause of these attacks is, as a matter of course, the uremic condition. As to the proximate cause, the authorities are divided. Most individuals afflicted with Bright's disease are subject to arteriosclerosis, and Senator holds that very often these focal disturbances are due to capillary hemorrhages. This opinion is shared by Wagner and Landois. That this may be true for some cases, especially those in which the paralysis does not disappear rapidly, can not be denied. But the autopsies which are on record seem to disprove this theory. Another theory advanced by Landois is that the paretic manifestations are the results of an exhausted condition of the cortical centers resulting from over-irritation resulting from the uremic excitation and subsequent convulsions. This theory, however, fails to explain the causation of those cases in which the Jacksonian epileptic attacks, the paresis or aphasia precede the uremic attacks or occur in uremia in the simple condition of coma.

There are but two possible explanations remaining: one is the toxic theory, and the other the theory of localized cortical edema of Traube. Traube's theory is the theory which ought to explain the occurrence of uremic convulsions in a mechanic way: as a result of edema of the brain there is produced a pressure upon the veins and capillaries which results in an anemia, consequently in a diminished supply of oxygen, and as a result we have the convulsions. Rosa (*Berlin Klin. Woch.*, Feb. 28, 1898) seems to think that it may possibly explain the focal symptoms of uremic attacks. Chantemesse and Tenneson seem to hold the same opinion, and Senator says that, "localized and circumscribed edema may explain the origin of uremic amaurosis and hemiplegia." The majority of authorities are agreed, however, that the uremic condition is the result of an autointoxication, and that the real cause of the manifestation is a chemic poison—urea, acetone or whatever it may be—which irritates the brain and produces the symptoms. But how does this bring us any closer to the answer as to how the focal symptoms are produced? We are once more thrown back on theory, for pathology reveals nothing to us. We know that certain parts of the cortex are more subject to the action of the chemic poisons than others, but if we wished to apply this to uremic conditions then the focal lesions ought to be

constant, occurring in every case of uremic convulsions. We can fall back on the old theory of individual idiosyncrasy, but it does not aid us much. Pierret and Senator hold that there may be circumscribed disturbances of circulation, a spasm of a vessel in a localized area of the cortex, resulting from some diseased condition of that vessel, such as arteriosclerosis. As a result of this spasm produced by the toxic condition of the blood, there is a localized ischemia with a subsequent parietic dilatation, stasis of blood, edema and intoxication of the cortex. Assenting to this theory, those areas of the cortex would be most likely to suffer which are supplied by vessels in a state of degeneration.

Baynaud and Pierret hold, and our Case 3 seems to bear out the statement, that focal manifestations due to old brain lesions, which, however, have disappeared, are apt to return as a result of all kinds of systemic infections and intoxications and especially in uremic conditions, which would seem to prove that areas of the brain weakened by some former insult and apparently recovered again, are more susceptible to intoxication than other areas which are normal.

PATHOLOGY.

The anatomic investigations of the fatal cases fail to throw much light upon the etiology of these attacks. They all agree in one respect, namely, that there are no gross anatomic lesions to be found in the brain or spinal cord. Prior to 1881 it was supposed that the hemiplegia occurring during uremic convulsions was always the result of a cerebral hemorrhage. Paetch, about this time, reported three cases in which the hemiplegia continued up to the time of death, and in which the autopsy was practically negative. In one case he reports the presence of an excessive amount of cerebro-spinal fluid and edema of the brain; in another the brain was perfectly normal. The former autopsy was made by Israel, the latter by Jurgens. Paetsch, who holds the theory of localized edema and serous infiltration, lays much stress upon the occurrence of the edema, but we see edema of the brain quite frequently without any paralytic symptoms during life. Dunin publishes another case which presented during life nystagmus diplopia and hemianopia, in which the anatomic examinations, both gross and histologic, were entirely negative. It is interesting here as a collateral proof of the intoxication theory of these focal lesions to refer to two published by Oppenheim (*Charité Annalen*, 1888).

The first case was one of hemiplegia with aphasia, the other a typical case of Jacksonian epilepsy, both being associated with carcinoma, one of the breast the other of the stomach. It was supposed during life that the occurrence of the manifestations on the part of the nervous system were due to the occurrence of metastatic growths in the brain. The autopsies were entirely negative; no changes were found in the brain. The author believes that the attacks were due to intoxication, and that poisons may affect circumscribed areas of the cortex of the brain.

DISCUSSION.

Dr. SEXTON—I think the considerations which were brought forward in the latter part of Dr. Hoppe's paper lead us really toward the truth in regard to the theory of most of these cases which he is inclined to classify as of uremic origin when hemiplegia is present. It is not quite clear to me how we can have a condition which must necessarily depend upon a local lesion in the brain, without that local lesion ever being demonstrable, and I think that the history of these cases as mentioned is somewhat negative in that direction. What I mean to say is that we can scarcely see the mechanism of the poison which is supposed to produce the hemiplegia. My own opinion would be that the great majority of these cases really depend upon a local hemiplegia, a rupture of minute vessels, in which the absorption of the clot is so perfect that after death the autopsies do not give any evidence of its existence. I do not think there is any doubt that we have many cases of hemiplegia which are due to small hemorrhages. The fact that a quantity of uric acid is found in the urine I do not regard as conclusive, because, as Dr. Hoppe mentioned, the condition of the kidneys favor these ruptures, and it is more plausible to explain the existence of the hemiplegia upon that hypothesis than upon the hypothesis that a limited area of the brain should be poisoned by the uremia, while the remainder of the brain escapes. I have seen a number of cases in which there was a transient hemiplegia, and a certain portion of these cases have albumin in the urine, and yet I was never able to satisfy myself that the presence of Bright's disease was the cause of the hemiplegia.

Dr. LODOR—It has been my good fortune or misfortune to see a great many cases of hemiplegia that I believe are uremic in their origin. I cannot believe with Dr. Sexton that there is an organic base for the origin of them. Uremic hemiplegia following childbirth is more common than most neurologists know. Following in the course of Bright's disease I have noticed those cases that have a rise of temperature—and a rise of temperature is almost entirely secondary—do not get well rapidly or get well at all. In cases that have no rise, or a small rise in temperature, the hemiplegia disappears quickly after the disappearance of the albumin. I cannot see how a hemorrhage could take place from a ruptured blood-vessel and disappear almost as if by magic, as these cases do.

Dr. TOMLINSON—I would like to add the evidence of my experience to confirm the conclusions of Dr. Hoppe's paper, and to call attention to three cases published by Dr. Burr of Philadelphia, in which the history was the same, and which appeared to be apparently true hemiplegia, and yet in which the autopsy showed nothing. In the last year I have had four cases which came to postmortem, and all these cases were cases of interstitial nephritis, with the same symptoms manifested as those described by Dr. Hoppe. One thing I noticed particularly was that the paralysis was not complete; that there were some groups of muscles that were not involved, and that it appeared and disappeared in different parts, coming and going from time to time. The face and the limbs would be paralyzed; the paralysis would disappear from the arm and become more grave in the face, and vice versa. I can also confirm the prognostic effect of the rise of temperature; it has been the same in my own experience. Another thing I have noticed in these cases postmortem, has been the intense edema of the floor of the fourth ventricle. I have concluded that the cause of death in these cases has been the result of this edema, from the uremic poisoning. In my own cases I was able to know of the existence of the nephritis for a long time before the paralysis appeared, and by careful examination to find all the indications of chronic nephritis. Since I have become familiar with them I have been able to almost anticipate these cases and to know what the result will be according to the extent of the nephritis. The recovery of the cases will depend entirely upon the stage of the nephritis. On postmortem, in spite of the most careful study, I have never been able to find any local lesion or disturbance to account for it. I have not made up my mind entirely as to vasomotor edema or vasomotor spasm. I am disposed to think there is a spasm which temporarily deprives that portion of the brain of blood.

Dr. ESKRIDGE—I rise mainly to call attention to the differential diagnosis of Jacksonian epilepsy due to organic lesion from these spasms, due to presumed functional disturbance of the cortex. When we have an organic spasm in the cortex, the muscles involved in the spasm are the last to be affected. The temperature is always high on the affected side, and the patient loses consciousness. I have not met a case of spasm, due to uremic poison, in which there has been much difficulty

in making the diagnosis between that and a limited cortical lesion. I have met with cases in which I was able to make an absolute diagnosis as to whether the paralysis was due to organic lesion or some functional disturbance. As we all know, a few hours' waiting clears the diagnosis in these cases. As a rule, in organic lesions of the cortex, only those muscles affected in the initial spasm will be paralyzed after the convulsion is over. In paralysis due to the effect of a poison, in nephritis and hemiplegia, paralysis of one arm and one leg is common.

Dr. C. EUGENE RIGGS of St. Paul—I think that Dr. Hoppe is to be congratulated on the exceedingly happy way in which he has put this very practical subject before the Section. I am inclined to believe, however, that there is a golden mean that Horace tells about, in which we can probably take a safer position than by saying dogmatically that these are simply due to toxemia, or simply due to hemorrhage. I confess to great sympathy with Dr. Sexton's view. We know that one-third of the cases of organic hemiplegia are probably due to Bright's disease; we know that Bright's disease produces hyaline degenerative changes, and slight pressure will cause this disaster. But we also know that the resulting phenomena depend entirely on the location of the hemorrhage. We all have seen these limited aneurysms in the brain, and if one of these aneurysms happens to break, the first effect is insult to the brain, in which you will find certain phenomena described by Dr. Hoppe, while in a very short time that will all pass away. I think that death may not only be due to the influence of uremia—you have all seen poisons so extremely toxic as to cause death in a short time—but it may also account for the temporary phenomena of paralysis. That seems to me a thoroughly clear and legitimate conclusion. As soon as the kidneys act thoroughly and properly the paralysis will clear up. While the uremic toxemia may account for a number of these cases, still there are a number of other cases due to hyaline fibroid degeneration of the brain.

Dr. C. C. HERSMAN of Pittsburgh—I can scarcely conceive the idea that these paralyzes are caused by hemorrhage. In one case that I saw, some time ago, the paralysis was so profound that I was almost persuaded to believe it was a genuine attack of apoplexy, but the clearing up was very rapid, only lasting a few hours. My surprise was, not that it cleared up so soon, but that it was so complete. It seems to me that if a lesion were present, we could scarcely expect such rapid recovery. It is possible, however, that a miliary aneurysm occurring, the profound shock to the part might be the cause of paralysis, and on recovery from the shock, the lesion not being extensive enough to cause a destruction of tissue would answer for the cause and the rapid disappearance. The theory as to vasomotor disturbance has been disputed by many; in fact, all the theories that I have seen suggested have been disputed by others. Consequently we can not say that we have any definite conclusion that we can hold to; but I am inclined to think that the cause is not a lesion or a hemorrhage, any more than it is in the case of epilepsy, or any other convulsion which we might have that is not caused by hemorrhage.

Dr. HEINS—I have noticed that the gentleman in speaking of these cases spoke of them as rather milder cases, and therefore allowed the possibility of recovery in that way. They speak of the percentage of albumin. A case of nephritis is not measured entirely by the amount of albumin that you have. If the gentleman says that 2 per cent. of albumin shows a small kidney lesion, then I would like to ask him what would be a larger percentage? I do not wish to be critical, but it strikes me it is a matter of some importance. It seems to me, too, that it is a bad thing for practitioners of medicine to cast away their anchors, and when you have, as Dr. Sexton has mentioned, an actual lesion that is the probable cause, to throw it aside. It is better to reason it out that way, than to say that there was no hemorrhage, because then you simply have no cause at all.

Dr. HOPPE—In answer to Dr. Hein's question about the percentage of albumin; as a rule the prognosis of kidney trouble is inversely to the amount of albumin present, the most fatal cases of interstitial nephritis being those that have the smallest percentage of albumin. Sometimes men will die without the urine showing any albumin. So the amount of albumin present does not have any bearing on the severity of the attack or the prognosis. The only difference about the paper seems to be as to the immediate cause of the condition in the cortex. We have actual facts at our disposal, and autopsies which have been performed by the best men in the world. I would call your attention particularly to the autopsies made by Jurgens and Israel in Berlin; not only did they make gross pathologic examinations, but they made histologic examinations, and not

any trace was found of any change in the cortex. This is the history, postmortem, of all the cases in which the hemiplegia continued up to the time of death. When the Traube theory of localized edema was still in vogue, some of the autopsies showed edema of the brain. But we know that we find edema even in the brains of drunkards without having any symptoms of paralysis during life.

OCULAR HEADACHES.

Presented to the Section on Neurology and Medical Jurisprudence at the Forty-ninth Annual Meeting of the American Medical Association, held at Denver, Colo., June 7-10, 1898.

BY WILLIAM H. WILDER, M.D.

Professor of Ophthalmology, Chicago Polyclinic; Instructor in Ophthalmology Rush Medical College; Surgeon and Pathologist Illinois Charitable Eye and Ear Infirmary; Ophthalmic Surgeon, Cook County Hospital.

CHICAGO.

This subject is such a large one, and the views and experiences of ophthalmologists as to the rôle played by the eyes in the causation of this important symptom are so diverse, that it is difficult to give it the careful consideration that it merits in the short time allowed. When we reflect upon the mysterious character of headache and the unsatisfactory explanations advanced to account for it, we can understand the difficulty the ophthalmologist encounters when he attempts to give a reason for the faith that is in him, and to correctly interpret his clinical data. Even the exact seat of the pain is not known. Who can say whether it is in the brain itself or in the membranes covering it? In acute inflammation of these membranes it is quite probable that the severe headache is caused by the irritation of the meningeal nerves, but that is entirely different from the functional affair we are considering.

Just what influence vascular dilatation exerts in the production of this neurosis is equally uncertain. If it should be true, as claimed by some observers, that sensory nerve-fibers exist in the vessels of the brain, we could understand how distention of these vessels would give rise to pain, even without the increase of intracranial pressure. It is not improbable that the congestion of the mucous membrane lining some of the accessory cavities of the nose is accountable for many of the frontal headaches coming on after excessive use of the eyes, and this view is strengthened by the clinical observation that such cases are relieved only when, with the correction of the ocular defect, there is combined suitable treatment for the diseased nasal mucous membrane. That there are headaches induced by eye-strain is undeniable, and the discovery that the relief of the strain is followed by alleviation of the pain marks a brilliant advance in our therapeutics.

Notwithstanding that other general conditions may underlie the development of this neurosis, and the ocular condition may be only one factor, still its presence may for the time be a dominant one whose correction will strongly influence the future history of the case. And should the headaches recur at some time subsequent to the relief of the eye-strain, such recurrence would not disprove the value of the treatment, but would prove that some of the other underlying conditions had become dominant factors. Such complex cases are not infrequent, and show the importance of careful examination of the eyes in all cases of headache in which there is any doubt as to the etiology.

In most cases of so-called ocular headache, there is a history of the pain coming on after either mod-

erate or excessive use of the eyes for near work, but to this rule there are numerous exceptions. For example, some cases of excruciating vertical or occipital headaches coming on without any reference to the use of the eyes are relieved after wearing appropriate glasses. One cannot be certain therefore that no ocular defect exists because pain does not manifest itself in the eyes, or because headache does not come on with or immediately after the use of them. I shall not consider headaches occurring in connection with inflammatory conditions in or about the eye, for this would be foreign to the purpose of the paper, but shall speak only of those caused by 1, exposure to bright light; 2, strain of the ciliary muscle (so-called accommodative asthenopia); 3, strain of extrinsic muscles from incoordinate action (the so-called muscular imbalance).

EXPOSURE TO BRIGHT LIGHT.

Cases are not infrequent in which there seems to be a hypersensitiveness of the retina, which may or may not be associated with other nervous manifestations, and in such cases there may follow on exposure of the eyes to bright light a pain in the head or in the back of the eyes. With such persons a headache results when they look continuously at brightly illuminated and glistening surfaces, such as paintings in a picture gallery, a brightly illuminated page, especially if the paper is finely glazed, or if they are exposed to the glare of the snow or of a white, dusty road. The light from the electric lamps also seems to be peculiarly irritating to some eyes, and sufficient at times to excite a headache. In many such cases an examination will show some refractive error causing strain of the accommodation, which will aggravate the difficulty, but in others no such trouble can be found, or the symptoms persist after the correction of such a defect so that we are forced to conclude that excessive irritation of the retina will act as a cause of headache.

Of course, such hyperesthesia of the retina might be a precursor of inflammatory change, in which case a slight congestion of the vessels in and around the optic disc and the yellow spot would be noticed. But in many the ophthalmoscope reveals no such sign of inflammation, while occasionally there is seen only on careful focusing, a peculiar finely-dotted appearance of the retina in the region of the macula lutea, very much as if a mixture of pepper and salt had been sprinkled on it. Whether this represents a beginning pathologic change in the elements of the retina, or is the normal appearance of a retina that is unusually sensitive I do not know.

STRAIN OF THE ACCOMMODATION.

This is the most important and frequent cause of ocular headaches. When the normal emmetropic eye looks at an object more distant than 20 feet, the rays of light from that object are brought to a focus on the retina and produce a clear image without any effort on the part of the muscle of accommodation. If the object is nearer than 20 feet, rays of light emerging from it will not be focused on the retina of the emmetropic eye without the aid of accommodation, and the nearer the object is brought the more accommodation will be necessary. At 20 inches 2 D of accommodation are necessary, at 10 inches 4 D, at 8 inches 5 D, at 5 inches 8 D and so on.

This accommodation is accomplished, as we know, by a change of shape in the crystalline lens, brought

about by the contraction of the ciliary muscle, and if this contraction is excessive there results a strain of this muscle, and even in certain cases a spasm of it, with resulting discomfort and sometimes headache. Children often contract a pernicious habit of sitting in a crouched position with the head bent forward close to the book, thereby putting a great strain on the ciliary muscle, and on account of the compression of the superficial veins of the neck, producing a congestion of the head which may lead to the development of myopia or even more serious complications. Often such children are precocious subjects—inordinate readers, as their parents will tell us—and of a nervous, restless temperament, and they are frequently brought to the specialist for eye-ache and headache. In some of them no error of refraction is discoverable, or the error is so small as to be quite insignificant, and they are benefited by correcting the method of reading and having them use the eyes less for near work.

The hypermetropic eye, by reason of its antero-posterior diameter being too short, is unable to focus parallel rays of light upon the retina, and accordingly accommodation is necessary to see even distant objects distinctly. This places an additional amount of work upon the ciliary muscle, and if astigmatism is also present, the strain is even more severe, for the muscle is constantly trying to correct the unequal meridians of curvature of the cornea, and is therefore contracting unequally. Such an eye is using its accommodation constantly, even for distant objects, and the work of the ciliary muscle is necessarily much greater when near objects are to be seen distinctly. In such a case the ciliary muscle undergoes to a limited extent a compensatory hypertrophy, and is able for a time to do the work assigned to it. But let its nutrition suffer because of impairment of the general forces of the economy, and that work becomes a burden that formerly was done with ease, and the unhappy subject is made aware of the presence of his eyes. Or if additional demands are made upon the accommodation, as for continuous reading, writing, or sewing, the muscle is found unequal to them, and pain is felt not only in the eyes but in the head. This is noticed also when the attention is closely fixed upon distant objects. Astigmatics frequently complain of headaches after going to the theater, or when traveling and looking at the passing landscape, or after a round of shopping.

In London they speak of an "Academy headache," the result of gazing intently at pictures during the exhibition. Such a headache may be partly due to the glare of the light from the brilliant colors on the canvas, and partly to the physical exhaustion incident to the loitering through a picture gallery.

Even slight degrees of astigmatism may be sufficient to cause considerable eye-strain under such conditions, particularly so if the astigmatism is of the oblique variety, in which the principal meridians of curvature of the cornea are no longer horizontal and vertical. The ciliary muscle seems to find greater difficulty in overcoming this kind of astigmatism.

When the individual is in perfect health he may be able to overcome a very considerable refractive error without experiencing any ocular distress, but if for any reason his vitality becomes impaired—particularly his nervous vitality—then he feels the additional strain, which may manifest itself in headaches. This is very noticeable in patients having hypermetropia

or astigmatism who are recovering from some severe exhausting disease, in young persons at the time of puberty, and in persons suffering from neurasthenia. A good illustration of this is to be found in a case of paresis or paralysis of the ciliary muscle following diphtheria. Even after the muscle partly recovers its power, it is very weak and easily becomes fatigued with slight accommodative effort, much more so if it has to overcome also a refractive error of hypermetropia or astigmatism, and this manifests itself by reflected pain in the head.

MUSCULAR INSUFFICIENCY.

We now come to the third cause of ocular headaches—the strain of the extrinsic muscles from lack of balance, so-called “muscular insufficiency” or “muscular imbalance.” This term assumes that one or a group of the eye muscles is too weak for its opponent, and there is therefore a tendency for the optic axes to deviate from the normal. This usually concerns the recti muscles, and of these the internus and the externus are the ones most frequently affected, although the superior or inferior rectus may show signs of weakness, and it is even claimed that at times the oblique muscles are at fault. If this deviation of the optic axes is apparent without tests, there exists strabismus, but if it is only latent, each eye fixing the object, and binocular single vision being present, it is spoken of as insufficiency of one or the other muscle. To this general condition the term “heterophoria” has been given by Stevens, and this is specifically divided into “esophoria, a tending of the visual axes inward; exophoria, a tending of the lines outward, and hyperphoria (right or left), a tending of the right or left visual line in a direction above its fellow.”

Diplopia is so dreaded by the mind, and desire for single vision is so great, that extra effort is made to compel the so-called weak muscle to keep the optic axes in the right direction, and this effort is supposed to cause an unequal strain on the muscular apparatus of the eye that may excite all kinds of neuroses. Headache, megrim, chorea, neuralgia, insomnia, chronic gastric and digestive disturbances, epilepsy, nervous prostration and insanity are some of the conditions that are supposed to result from such eye-strain; and it has even been claimed of late by some of the enthusiasts in this work that an organic disease like trachoma owes its origin in many cases to insufficiency of some of the eye muscles. It is much more difficult to determine the effect produced upon the nervous system by strain of the extrinsic eye muscles, than it is to demonstrate such effect by strain of the ciliary muscles, even with extensive clinical data at hand. In the first place, the tests for heterophoria are not so accurate as those we use for estimating the refraction of the eye, and in the very nature of things they can not be. In the second place, we are dealing with a muscular apparatus far more complex than that which controls accommodation—a muscular apparatus which is innervated by three distinct motor nerves and is intimately connected with the sympathetic system; a muscular apparatus which is double, and must perform wonderful co-ordinate and conjugate movements.

It is extremely difficult to determine with positiveness whether the muscular insufficiency is due to weakness occasioned by organic defect of the muscles themselves, whether it is due to imperfect innervation of the muscles because of some trouble in the nucleus,

or whether it concerns some of the higher centers presiding over co-ordination. In many cases it is even impossible to say whether a given muscle is too weak or its opponent is too strong. In the third place, we have not yet obtained accurate data as to the normal limits of mobility of the eye, and we are therefore not in a position to fix the abnormal.

The assumption that normal abduction must be sufficient to overcome a prism of 8 degrees and normal adduction equal to a prism of from 30 to 50 degrees is purely an assumption. While I am not prepared to deny that heterophoria or muscular insufficiency may in some cases be the cause, or one of the causes, of headaches and other neuroses, yet I hold that the results obtained by many ophthalmologists in the treatment of these cases, and adduced as proofs of the proposition are very far from conclusive. It is true there are cases in which operation on the muscles of the eyes seems to have accomplished results that are indisputable. I have had a few such cases myself, but the majority of them present such complex nervous symptoms, sometimes verging on the hysteric, that it is difficult to say whether, in treating the muscular anomaly, we are attacking the disease itself or only one of its effects.

In considering the location or variety of ocular headache it is impossible to specify any positive characteristic that will differentiate it from headache arising from other causes. In general we may say that the headache brought on by eye-strain is of a dull heavy character, although at times it may be sharp, excruciating and neuralgic, sometimes being so severe as to cause nausea or vomiting without its being a true megrim. Its most frequent seat is in the supra-orbital or frontal region over the frontal and ethmoidal sinuses, a brow-ache, or it may be described as a pain in the back of the eyes or deep in the orbits. The next most frequent location is in the temporal region, and the pain here may be throbbing in character. Occipital headaches are also observed, the pain being sometimes referred to the base of the skull or the nape of the neck, and even reflected to the back and shoulders. Ocular headaches affecting the vertex are, in my experience, less frequent than any of the others.

The most characteristic sign is the occurrence during or after excessive use of the eyes, as in reading or other near work, sight-seeing, shopping, etc., but, as I have mentioned before, this rule is by no means absolute. A person may awake in the night or rise in the morning with a headache apparently excited by an uncorrected astigmatism. As far as true megrim is concerned, my observation leads me to believe that eye-strain, whether accommodative or muscular, is much less frequently a cause of it than of any other variety. It is true that the attack may be aggravated by a refractive error, but I have seen so many severe cases in which no error or muscular anomaly existed, that I am constrained to believe that when such errors are present they do not act as a direct cause of the trouble.

TREATMENT.

As far as regards the treatment, it may be summed up very briefly. Every case of headache, the etiology of which is at all obscure, should receive a careful examination of the eyes, and this should include a most complete examination of the refractive condition as well as a thorough study of the action of

the muscles. Nothing short of an examination by the use of a mydriatic that will completely paralyze the accommodation is sufficient, as it is impossible to discover low degrees of hyperopia and astigmatism if the ciliary muscle is active. Lenses representing the full correction of the refractive error, less .25 or .5D, should be prescribed and their constant wear insisted on. They will not be tolerated unless the eyes are under the influence of a mydriatic, but with its help the eyes adapt themselves to the new relation. Some persons will be able to lay aside the glasses after the functions have returned to normal, without the recurrence of the headaches, or any of the symptoms that prompted their use. This is often noticed in certain cases at the age of pubescence, at which time the nervous equilibrium being so unstable, headaches may occur because of any excitement or irritation, and a slight hyperopia or astigmatism may furnish the cause. The correction of this defect by relieving the ciliary strain, may remove one of the factors and so prevent the headaches.

In cases where the trouble is not relieved by such measures, and it has been determined that a muscular anomaly exists, this should be treated by prisms, exercises, and means to strengthen the weak muscle before its apparently stronger fellow is operated upon.

In conclusion, I wish to emphasize a few of the points made in this paper:

1. There may be headaches which we may be justified in calling "ocular headaches," for in many of them there seems to exist a demonstrable causal relation between the eye-strain and the neurosis. Just how this operates it is impossible to explain at the present time. Possibly when the presence of sensory nerve-fibers in the walls of the blood-vessels of the brain has been demonstrated, such an explanation as the following may be plausible: "The irritation of the sympathetic nerves in the ciliary body by constant contraction of the muscle and the presence of the products of metabolism, causes through the vasomotors a contraction of the blood-vessels, followed by a dilatation and distention with resulting irritation of the sensory fibers."

2. While there may be a number of underlying conditions at work to cause a headache, eye-strain of any kind, if present, may be a dominant factor exciting the attack, or in aggravating it, and the relief of this strain will often exert a most favorable influence.

Finally, no study of headache is complete that does not reckon with the conditions that may exist in the eye, and when etiology is not perfectly clear these conditions should receive careful attention.

DIAGNOSTIC CHARACTERISTICS OF HEADACHES ACCORDING TO THEIR ORIGIN.

Presented to the Section on Neurology and Medical Jurisprudence, at the Forty-ninth Annual Meeting of the American Medical Association, held at Denver, Colo., June 7-10, 1898.

BY H. GRADLE, M.D.

CHICAGO.

The object of the present paper is to point out those peculiarities of headaches which can serve as guides in the search for their origin. The author's experience pertains principally to headaches dependent upon affections of the special senses. But valuable lessons, too, have been learned—in a negative

sense—from the study of those cases which, on investigation, proved to be of different character.

Before proceeding to details, I wish to explain the point of view from which I have been led to regard headaches of peripheral origin. While I agree with the general experience, that a large number of headaches start from some anomaly of the eyes or of the nose, I do not think that the detection of such a peripheral origin ends the investigation of the case. We must consider not merely the peripheral lesion, but also the condition of the nervous system. There are, indeed, certain peripheral conditions which will necessarily cause headache in every case; for instance, acute inflammation of the ciliary body, or acute supuration of the nasal sinuses. But, on the other hand, inflammatory affections of a more chronic character and mere refractive anomalies lead to headaches only in some, but by no means in all patients. As I have elsewhere shown (*New York Medical Record*, Dec. 17, 1895), the difference in the symptoms hinges on the condition of the nervous system. Errors of refraction do not cause headaches in absolutely normal subjects, they simply produce local discomfort in the eyes. In those instances in which optic defects lead to headaches we can demonstrate a neurotic tendency by close examination of the patient, his family record, his personal history, or sometimes only his subsequent history. The more pronounced the instability of the nervous system, the more likely will comparatively trivial peripheral disturbances lead to headaches.

The characteristics of headaches are: 1, their location, and 2, their time-relations. Their severity is a less reliable guide for evident reasons.

Location.—The most important question concerning the site of a headache is whether it is wholly or predominantly one-sided. One-sided headache is always due to a lesion on the same side of the head, either intracranial or in one of the organs of sense. The only exception is that form of migrain which, though one-sided at the time, alternates regularly between right and left, for in this case the source is not one-sided, if it be peripheral at all. Conversely, however, one-sided lesions may in some instances cause headache not limited to the same side. This is sometimes true of unilateral errors of refraction, as well as of affections of one ethmoid or sphenoid cavity. Apart from the side of the head, the location of a headache furnishes no positive indication as to its source. Although headaches are, as a rule, located in the vicinity of the organ whence they are started, there are so many exceptions to this rule, especially in neurotic subjects, that it has but little diagnostic value.

Time-relations.—From the point of view of their time-relations, headaches can be classified as: 1, paroxysms recurring at *a*, irregular or *b*, regular intervals; 2, attacks following some specific act; 3, more or less continuous pain. In this connection, too, must be considered the date of suffering, and its manner of onset.

1. *a*. Paroxysms of headache of similar intensity and duration and occurring at variable intervals constitute the form called migrain. The experience of oculists is very definite regarding the ocular origin of many instances of migrain. How large the proportion is, the oculist, however, can not state, as his cases are relatively selected. If wholly or predominantly one-sided, migrain is surely dependent on

either an error of refraction, or, in a smaller proportion of cases, on some nasal disease. The only ocular anomaly to which I have personally been able to trace migraine, is astigmatism. Hypermetropia does not cause it. Regarding the so-called muscular anomalies, I have no definite experience. If there are eye symptoms, and especially if the migraine is on the side of the notably weaker eye, an ocular origin is very probable. Still, the absolute proof in a given case can only be furnished by the influence of glasses. Even when astigmatism is present, it is not always the cause of the migraine, and in some few instances optic correction proves disappointing. On the other hand, the absence of eye symptoms does not preclude the existence of a moderate degree of astigmatism as the starting-point of the headache. The form of migraine preceded by scintillations and dim sight—the *scotoma scintillans*—is not always of ocular origin, although often the result of astigmatism.

Migraine is in relatively rare instances induced by nasal disturbances. Gruenwald quotes some convincing instances of ethmoid and sphenoid suppuration. My own experience, however, has included but few cases of well-defined migraine depending on such disease. When Hack made his startling statements, about fifteen years ago, concerning nasal reflexes, he quoted a number of cases of migraine prevented by cauterization of the nasal cavernous tissue. These observations do not seem to have been confirmed to any extent. I have personally seen one-sided migraine occurring in connection with nasal stenosis of the same side. In three of these instances I was able to furnish a proof of the relationship, by the great improvement in the severity and frequency of the attacks after operative removal of the stenosis, but in none of the instances were the paroxysms entirely averted. Migraine of moderate severity and relative infrequency occurs in persons of apparently normal nervous system and good family history. But great frequency, great severity or massing of separate paroxysms into a continuous spell indicate other factors exerting a depressing effect upon the nervous system, besides a possible peripheral origin in the given case.

b. Paroxysms of headache with regular periodicity—recurring about the same hour daily—have mostly been the result of sinus disease in my experience. In most of these instances the pain should really be classified as a neuralgia. If, however, it is not strictly confined to a small area of nerve distribution, the patient may describe it as a headache. I have seen it in connection with acute or subacute inflammation of the various nasal accessory cavities. When starting from the frontal sinus it appears as a supraorbital neuralgia, which, however, may radiate into a diffuse one-sided headache. The diagnosis is not always easy, even on inspection, for suppuration of the frontal sinus of moderate intensity is sometimes almost latent, and often transient, though recurrent. But there was always the history of a preceding acute coryza. These attacks yield quite often to either quinin or antipyrin, even where there exists demonstrable sinus disease. In ethmoid and sphenoid disease the pain is more described as headache than as a circumscribed neuralgia—usually but not invariably one-sided.

2. Of headaches following specific acts the most characteristic is the pain brought on by the use of the eyes for near work. The more precise the coin-

cidence of headache with eye-work, the more probable is the origin in either hypermetropia, hypometropic astigmatism, or myopic astigmatism—in the order mentioned. I do not mean that this order represents the frequency of the three anomalies, but the probability of a headache occurring irregularly and not strictly proportionate to the amount of eye-work increases in the order mentioned. The more neurotic the subject, the greater the probability of headache occurring at irregular occasions during the day, but these eye headaches are never present on rising, and never severe enough to prevent sleep. In any deviations from this rule other factors must be sought for. In highly neurotic subjects these ocular anomalies may bring on headaches on using the eyes even for a distant fixation, as for instance, in the theater. Finally, there are rare instances, generally in anemic, sometimes in hysterical, patients of headaches following strictly upon the use of the eyes where no ocular anomaly of any kind exists.

3. Headaches more or less persistent, or with irregular intermission may result from the same optic anomalies, but only in run-down subjects. Very often other assisting factors can be demonstrated, such as stomach or intestinal disease, loss of sleep, and particularly insufficient out-door exercise. In other instances the refraction may be perfect, but other ocular disease be found. This is sometimes a peripheral choroiditis. Not rarely too, do we find the granular or salt and pepper appearance of the fundus, which I described last year (JOURNAL AM. MEDICAL ASS'N., Jan. 29, 1898), in connection with a highly neurotic disposition. It has seemed to me rather characteristic in such instances, that the pain begins at once on awaking. Continuous one-sided headache if at all connected with the eye, is usually indicative of some serious inflammatory condition, especially if of recent date and rapid onset. Optic neuritis—especially the retrobulbar form—is to be thought of, even if dim sight is not specifically stated by the patient. The most serious condition that may lead to such symptoms is glaucoma and the possibility of chronic glaucoma, as the cause of severe and persistent one-sided headache should not be lost sight of.

Among nasal diseases the forms most likely to lead to persistent and unusually severe headache, are the more intense suppurative inflammations of the sinuses, in which case nasal symptoms can always be elicited. Nocturnal aggravations are not uncommon under these circumstances. Moderate but very persistent headache is occasionally complained of in nasal stenosis of any kind, but only by distinctly neurotic subjects. It is less generally known that inflammatory conditions of the pharyngeal tonsil are sometimes the source of continuous headache, usually not very severe, in both children and adults; in fact, the existence of such transient inflammations in this region is not yet generally recognized. I have seen over a dozen instances where the postnasal mirror showed either the existence of scattered white spots of exudation comparable to lacunar tonsillitis, or suppuration with scabs on the abraded surface at the roof of the pharynx. In most of these instances I was able to stop this headache by appropriate local treatment. I will add finally, that I have seen two instances of persistent, diffuse one-sided headache with irregular exacerbation which could not be traced to any peripheral source except carious teeth, and which ceased promptly after their extraction.

DISCUSSION.

Dr. FRANK P. NORBURY, Jacksonville, Ill.—I think the question of localized headaches is one that should be considered in a broader light than we have had it presented here to day; that is to say, aside from the question of the influence of the eye or of the nose. We frequently meet cases of persistent headache, localized headache, which on examination may not reveal errors of refraction or nasal disturbance, but which nevertheless are persistent and give rise to a great deal of concern, both on the part of the patient and on the part of the physician. We are consulted to relieve the patients from these distressing headaches. I think in all cases presenting persistent headaches it is our duty to go beyond the examination of the eye or the nose or the ordinary neurologic examination; that is to say, we should go into it from the standpoint of internal medicine, because it has been our experience that these conditions can only be relieved, in many cases, by a treatment of the patient as an individual. In one case in particular, a case of diabetes, there was a persistent headache associated with urinary symptoms. The diabetes had not been diagnosed. I subsequently made a diagnosis of diabetes, and the subsequent treatment, regulations, etc., relieved the patient of his headache.

Again, in cases of lithemia—so called uric acid cases—we meet a great many of them with localized headaches; the migraine not altogether limited to one side, varying from side to side, but they are essentially cases that can be relieved and oftentimes relieved speedily, and with permanence, if proper treatment be directed. The lithemic headaches are not unusual with school teachers or in the office men who are confined to their desks, and in persons occupying positions of responsibility wherein they have to use a great deal of mental power, and it is not unusual to find in many of these cases that the headaches are of lithemic origin and can be relieved, and relieved speedily. In Central Illinois, and in fact in the Mississippi Valley, we are apt to meet many cases of headache that are of malarial origin, this being determined by blood examination. Cases which have failed to yield to the ordinary treatment of correction of refraction, or of errors involving the nose, when placed on malarial treatment, are immediately relieved. Then, it is not infrequent to find in some forms of insanity a persistent localized headache. I allude especially to those forms of insanity that are due, say, to valvular disease of the heart. It is probably a rare form, but nevertheless there are cases of insanity due to changes either in the heart or in the arterial system, and I remember one case in particular where valvular disease of the heart was responsible for innutrition of the brain, which, when properly treated, relieved the patient not only of the headache but of the insanity as well. There are cases due to simple anemia, occurring during the adolescent period, and especially in girls. The headaches at that period sometimes, as you know, interfere greatly with young women in their work at college. In young women taking a course in the arts, where application must be constant, the headaches become so violent as to interfere with their studies. Of course, a headache is simply a symptom, and in our investigation of headaches we must be very careful to take into consideration the possibility of all diseases, applying in our diagnosis all the tests we possibly can before we arrive at our decision.

Dr. ROBINSON of Illinois—This is a subject in which I have great interest. I have looked at this subject of headaches, and watched the cases which have been brought before me for many years, including those that are sometimes called headache and sometimes migraine. The causes and treatment are beyond my caliber to understand. I know one family the members of which have had that form of headache for thirty years, occurring every two or three weeks, and the father, son and daughter, for four generations, have these attacks. I have in mind now one case where the patient has been suffering for more than thirty-five years with headache, which at first would come on by a pain over one eye, or a blindness. At the present time the attacks commence usually in the night, and in the morning the headache becomes more severe, and the patient is obliged to keep her bed from 24 to 72 hours. Nothing seems to relieve these paroxysms except morphia, and that only temporarily. The acetanilide, the stimulants, caffeine, and all the medicines I have used, produce only temporary results. I have looked upon these headaches from the standpoint of uremic or uric acid poisoning, and I do not know but that may have some influence. But they recur regularly. In one case the patient will wake up about 2 A.M. with a severe headache. He either gets up and goes around town the next day, or takes a dose of acetanilid, caffeine, bromid, or soda, which will frequently relieve the headache for two or three

weeks. But the poison seems to be bottled up in the system, and breaks forth to such an extent that a strong man is a wreck, unable to do anything, and suffering more than I can describe.

Dr. ESKRIDGE—An interesting form of headache is suspended or postponed headache. I have not infrequently noticed that school children will go all week without suffering, and on Sunday invariably have a headache. The same is true of book-keepers, who will invariably be attacked with headache on Sunday. This can be explained on the same theory that a person carrying a grip or other weight, getting accustomed to it, does not notice it until he puts the grip down. As to migrainous headache, I think we have to look for the cause first, to a defect in the constitution—a defect in the neural structure—and next to some defect probably in the nutrition; but the whole pathology is not known.

Dr. J. W. GIVENS, Black Foot, Idaho—The significance of headache to the patient is one of the things that we all have to confront in our daily practice. The label "headache" is very indefinite, but nevertheless it is the description of the condition of which the patient complains, and the one that we are called upon to relieve. I am sure what Dr. Gradle has said in regard to nasal trouble is true. We notice this fact in this mountainous country, where we have more or less catarrhal trouble. I feel that by attending to and relieving the nose we do a great deal toward relieving the headache. I also think that these wind-storms are responsible for a good many headaches. Then, too, as Dr. Eskridge has said, a great deal of headache is constitutional. The pathology of it in many cases is something like the pathology of epilepsy. We do not know what it is; but the headaches are, in their clinical picture, very like the picture of epilepsy. I do not know what can be done for those cases any more than I know what can be done for epilepsy. Most of them have to be endured. In all cases of headache I think we shall generally find a lowered condition of nutrition, and while the local conditions—the nose, the ear, the teeth—require attention, it is very important to keep the general health up to the very highest point of excellence by the use of pure food, outdoor life as far as possible, the use of cod-liver oil and the tonics, treating the patient, in fact, as we would treat a thorough-bred race horse, if we wanted him to win the race. Treat the patient in this way and keep him in that condition all the time, and you will minimize the likelihood of headaches, or at least reduce their severity.

Dr. WOODSON of Missouri—I have frequently found that headache occurs in anemic conditions, especially in chlorotic girls and in children that eat irregularly or that do not take time to eat, owing to their eagerness to get out to play. I have also found headache occur in persons who give away to fits of anger, or in persons who attempt to overwork themselves, doing as much in one day as they ought to do in two; in persons who sleep in apartments that are not supplied with a sufficiency of fresh air. I also have frequently found headaches associated with catamenial disturbances, and we find it associated with the lesions of specific troubles. So far as giving a fixed prescription for headache is concerned, it would be as impossible as a fixed prescription for any other trouble. As suggested by Dr. Norbury and concurred in by others, it is necessary to look out for the cause, and if possible remove it; in the anemic and chlorotic, insisting upon a sufficient amount of outdoor exercise, and well-ventilated sleeping apartments, with a bountiful supply of nutritious food, and so on throughout the other cases.

Dr. HAROLD N. MOYER, Chicago—I take it that Dr. Gradle's paper was not on migraine at all, that being only incidentally referred to. I suppose his title would have been more nearly correct if it had read, "Characteristics of some headaches according to their origin." But the particular kind of headaches to which his paper referred were those of ocular and nasal origin very largely, and how to differentiate those from one another, and also from neuralgia and the headaches of other origin, I take it, was the purpose of the paper. There is one valuable point in the whole discussion, and that is the conclusion at which Dr. Gradle arrives from his standpoint of the ophthalmologist, one who largely sees cases of eye and nasal trouble primarily. My experience is entirely from the other side, but I substantially agree with his conclusions. I believe that fully 70 per cent. of all the cases of headache that I see are primarily eye-strain headaches, and I would put myself in accord with Dr. Gradle's conclusion as to the indication by which we are to arrive at a diagnosis. Since the subject of migraine has come up, I might mention that I have recently seen a very interesting case suffering from an eye strain. This persistent eye-strain was relieved by the proper glasses, but the patient still has her migraine at stated intervals, showing that there were two kinds of headache present in the same

patient. As to migrain, there is no doubt that in all these cases we are dealing with toxemia, and I think that the investigations of Ratchford have shown conclusively that it is not uric acid, but some of the by-products, and I am satisfied that is the underlying condition in most cases of migrain. However earnestly you look for end-organ disease, however you eliminate eye-strain, there will be a very large proportion of headaches in which you will not discover the cause, and which you will fail to relieve.

Dr. HUGH T. PATRICK, Chicago—I should like to ask one question of Dr. Gradle. I understood him to say that one-sided migrain was due to eye or nose trouble in all cases. If he meant that statement, I wish to very positively and emphatically dissent from it. If he says that one-sided migrain *may* be due to eye or nose trouble, I agree with him.

Dr. C. C. HERSMAN, Pittsburg—Quite a number of times in cases of headache thought to be due to eye trouble the headache was not benefited by correcting the eye trouble. I think, as Dr. Meyer stated, we will find the trouble due to a toxemic condition. In some cases of angioneurotic edema we have excruciating headaches; it is almost impossible to relieve them without very heavy doses of narcotics, and while we have very little light on angioneurotic edema, still I think that is a toxemic condition. In this trouble sometimes the swellings come on close to the monthly period, or we may find it two or three times during the month. A great many of the headaches are attributed to improper food and irregular habits; but if you take these same patients and make them live the most correct life possible for them to live, the attacks will occasionally occur. I do not understand the reader as Dr. Patrick understood him. I understood him to say that when we did have a one-sided headache it was most likely to come on the side of the bad eye.

Dr. T. D. CROTHERS, Hartford, Conn.—There are two facts that I think are very prominent. I think all these cases of headache are practically poison and starvation cases. The whole philosophy turns on that, and if you can eliminate these two elements you are successful.

Dr. CHARLES H. HUGHES—The chair would like to remark that the phenomena of headache are too much viewed from one spot rather than from the whole individual. Any one who has had experience with migrain, of which I have had an abundance for twenty years, knows what constitutes migrain. In my own case I was in the habit of forcing mental action to the utmost limit by the use of coffee. For twenty years of my life I used a half-gallon of coffee between 9 o'clock and bed-time, and forced myself to a condition of wakefulness. I always slept in spite of coffee, but I learned afterward that I did not sleep in each twenty-four hours quite so much as was necessary for daily recuperation. My migrain came upon me in this way: first at the end of thirty days I was obliged to retire *hors de combat* for about one day; could not tolerate the light; so hyperesthetic that I could not tolerate sensation of any kind. The greater part of that day was spent in misery and retirement. Then the conservatism of nature asserted itself; the sleep which followed, and which was more than I was in the habit of getting, was a compensation, and I was restored to a more normal condition. When it became my misfortune to preside over the fortunes of a lunatic asylum these migrain attacks came on every week, and the only thing that conserved my vitality at all was the very fact that it knocked me out so completely that I could not do anything for nearly one day a week. The toxemic theory has found a very satisfactory lodgment in my mind. I have no headaches now, and have not had for fully ten years; but I have learned to take care of myself better. The amount of brain strain that a man puts upon himself is sufficient to bring about this condition of the accumulation of toxins, and they cause the trouble, as I think is no doubt the case in our epileptic conditions; but it is necessary to have an organism that is predisposed. Exophoria, esophoria, errors of accommodation and refraction of various kinds are associated conditions, and they tend, where you have a neuro-pathic condition that gives you the headache, to make the latent condition active; but I do not think, as the ophthalmologists assert, that they are every, the sole, exclusive and only cause. As Dr. Brower said, the removal of whatever source of irritation that may exist is good therapy; it is good practice in neurotherapy as in every other department of medicine; but to assume that these migrains are the result of just one thing is a mistake in my judgment. As to medical treatment of my headaches, I learned to use bromid of potassium, afterward bromid of sodium, and I learned to get more rest and to adjust the expenditure of nerve force to my capacity for daily accumulation. The same condition that will give you a diabetic urine will, in the cortex, in the meninges, give rise to a headache; but it seems to me that this whole subject is a sub-

ject concerning the treatment of the individual and his habits. Irritation in the eye will bring out a latent headache.

Dr. HAROLD N. MOYER, Chicago—Is it not true that nine-tenths or more of the migrains practically cease with advancing years?

Dr. HUGHES—That is a fact, I think. At 45 years of age the majority of people cease to have migrain. At that time of life when they begin to understand what life is.

Dr. MOYER—And when their blood-vessels get a little harder?

Dr. HUGHES—That may possibly be the explanation.

Dr. GRADLE—I was not presumptuous enough to come before a Section of Neurologists with a paper on the treatment of headache. My paper merely had to do with the characteristics of some headaches which were relieved by local treatment. I wished to present those symptoms by which the peripheral origin can be determined, and relief obtained. Dr. Patrick did not understand me correctly. I said in the paper that in every case of one-sided headache the cause was either a one-sided intracranial lesion, or an affection of an organ of special sense on the same side. I base this on my own experience. I have never seen an exception to this rule. I was always able to trace such a condition to some affection of one side of the head, with this exception, however, that those cases of migrain which alternate regularly between the right and the left side do not come in the category; they are not due to one-sided lesion, or any other lesion. I have been misunderstood as to the importance of the peripheral lesion in causing headache, especially migrain. I stated in my paper explicitly that in every case of headache, not only the alleged peripheral causes but also the condition of the nervous system needed investigation. I added, furthermore, that there are some peripheral causes so potent that they would introduce headache in anybody, no matter whether they be in good health or not. For instance, a severe injury to the eye, causing inflammation, will invariably produce headache; or severe coryza extending into one of the sinuses of the nose will cause headache as a regular consequence, no matter how perfect the nervous system of the individual. On the other hand, an astigmatism of one diopter or thereabout will not necessarily give eye symptoms to a normal individual, whereas if the individual is run down, or other depressing factors are at work, he will have eye symptoms.

The question has been asked about the frequency of astigmatism as the cause of migrain. That the oculist can not answer, as his cases are selected. In the great majority of cases that were sent to me I was able to demonstrate an ocular origin, but, of course, only those cases came to me where a peripheral origin was suspected. I presume that a large number of cases of migrain have no peripheral origin. The proof is very definite that the peripheral irritation is sufficient to bring on these attacks. That other factors are present, also, there can be no reason to doubt, because of the periodicity of the attack. There must be some other factor. My paper did not deal with the pathology of headaches; I did not refer to these factors, and I am not at all sure that the toxemic theory is sufficiently proven.

In answer to Dr. Hughes' query as to cases of astigmatism coming on in school children while they are at work, and disappearing when they leave school for the term, I would say that the astigmatism does not really disappear; the astigmatism is stable in the majority of its conditions; the others are very rare cases. The strain is lessened when the child is at liberty. I consider it very one-sided and altogether wrong to finish the work by prescribing glasses, and not to consider the other factors at all. Of course, if the glasses relieve there is no reason why they should not be given.

EYE SYMPTOMS OF BRAIN TUMOR.

Presented to the Section on Neurology and Medical Jurisprudence at the Forty-ninth Annual Meeting of the American Medical Association, held at Denver, Colo., June 7-10, 1898.

BY EDWARD JACKSON, A.M., M.D.

OF DENVER, COLO.

EMERITUS PROFESSOR OF DISEASES OF THE EYE IN THE PHILADELPHIA POLYCLINIC, FORMERLY SURGEON TO WILLS' EYE HOSPITAL.

PHILADELPHIA.

OPTIC NEURITIS.

Among the eye symptoms of brain tumor we naturally think first of optic neuritis, the most striking and significant symptom in cases of this class. Probably not a few practitioners have associated optic neuritis chiefly or wholly with intracranial disease or

intracranial growths. But while it is right that great importance should be attached to this symptom, occurring as it does in 80 or 90 per cent. of all cases, it is necessary to point out that its discovery is far from establishing a diagnosis of brain tumor. It is of very little value to indicate the location of the tumor, and it is worthless as regards revealing the nature of the growth. But it does show with great probability that brain symptoms accompanying it are due to serious organic disease. Even here, however, its indication is not absolute, for, in common with these symptoms, it may arise from different kinds of poisoning.

It has been a matter of some surprise in going over a series of my cases of marked optic neuritis, to find how exceptional has been its connection with intracranial growths, and how many cases occur in connection with other diseases. Thus, among 27 cases, but 17 were probably connected with serious organic diseases of the brain and its membranes, and only 8 of those were—probably five or certainly three—cases of brain tumor. The others arose in connection with renal and vascular diseases, syphilis, various toxic agents, chiefly lead and alcohol, disease in the orbit, or of the ethmoidal and sphenoidal sinuses, or were of such obscure etiology as to be classed as idiopathic.

Unfortunately, optic neuritis due to brain tumor presents no especial characteristics that separate it sharply from optic neuritis due to these other causes. Indeed, it is sometimes difficult to distinguish it from such an entirely different condition as the optic neuritis due to eye-strain, or from the protruding opaque optic disc that occurs in rare cases, probably as a congenital anomaly. So far is optic neuritis from fixing the underlying pathologic condition as one of brain tumor, that in determining the cause of the optic neuritis the other symptoms of the case have to be carefully considered. Still the ophthalmoscopic appearances do give certain indications of the cause of neuritis, which are of value in reaching a diagnosis.

Let us contrast the neuritis due to the various other conditions mentioned with the typic optic neuritis of brain tumor. Such typic neuritis is characterized by great swelling, sometimes 10 or 12 D (3 m.m.), abruptly limited, at no great distance from the margin of the disc, with arteries narrowed, veins dilated and very tortuous, and small vessels much enlarged, but not very numerous, because scattered through the swollen tissue; and small, flame-shaped hemorrhages upon or near the papilla. The other portions of the fundus, except for the alteration in the vessels, are normal, or present changes which are slight as compared with those at the disc, although to this last statement there are very important exceptions.

In contrast with the above: Swelling and discoloration of the disc, occurring as an anomaly, are never of very high degree. No such recorded case showed more than 4 D. swelling of the optic papilla, and in none that I have encountered was the most and prominent portion of the swelling more than 3 D. in front of the level of the neighboring fundus. Again, even with the higher degrees of such swelling the retinal vessels are normal; and the other parts of the fundus are normal, or exhibit no lesions like those of neuro-retinitis.

Optic neuritis, due to eye-strain, is more common, but in this also the swelling is limited. The disc may be very red and yet the most prominent vessels be not over 1 D. in advance of the fundus. In this form, too, the larger vessels are but slightly altered, and the

fine vessels of the optic disc are very much more numerous, but are not particularly irregular in caliber or very tortuous.

Under idiopathic optic neuritis, or optic neuritis of unknown causation, I should prefer to place the unusual but not very rare cases that have been ascribed to cold, rheumatism, disturbance of menstruation, etc. The ophthalmoscopic appearances resemble those of optic neuritis due to eye-strain, except that the swelling may be greater and the retinal circulation more interfered with. Optic neuritis of this kind is usually acute, and tends to early and comparatively complete recovery. The field of vision does not present great concentric or irregular contraction as compared with the ophthalmoscopic appearances, although the blind spot may be markedly enlarged and irregular. I have met with one case in which such optic neuritis, with great impairment of vision recurred, yet was followed by almost complete restoration to normal.

Optic neuritis in connection with gummatous growths is rather frequent in the tertiary stage; but it may also occur as one of the earlier secondary lesions of syphilis. I have seen it within three months after the initial lesion. In this stage it presents the clinical appearances of idiopathic optic neuritis and is rather promptly amenable to treatment. Of the form of retro-bulbar optic neuritis that leads to central scotoma without marked ophthalmoscopic changes it is unnecessary here to speak. But in rare cases, certain toxic agents, especially lead, may cause a form of optic neuritis that closely simulates that due to brain disease. It is usually chronic, and attended with great swelling and corresponding disturbance of circulation, while the general condition of the fundus remains, as in the optic neuritis of brain disease, comparatively good. I know of no signs by which one may, with the ophthalmoscope, discriminate between this form and the optic neuritis due to brain tumor. The diagnosis between must be based on other symptoms, that should be constantly borne in mind in connection with this subject.

But most frequently the doubt as to the significance of optic neuritis rests upon the resemblance of the lesions in certain cases of renal vascular disease, to those connected with brain tumor. The forms of optic neuritis due to these two causes may in typic cases be quite distinct, and in the majority of cases there is exhibited a certain divergence of type. But in some it is absolutely impossible to decide from the ophthalmoscopic examination to which class the particular case belongs; and in some, neuritis due to the one cause inclines rather to the clinical type of the other. The typic differences are these: Optic neuritis due to renal and vascular disease is more apt to be attended by hemorrhages and patches of exudation throughout the fundus; is more apt to be accompanied by the stellate grouping of white spots at the macula; is more apt to be associated with marked irregularities in the caliber and appearances of the vessels, apart from dilatation and tortuosity of the veins. Still, optic neuritis from brain tumor may be accompanied by general retinal hemorrhages and considerable areas of retinal exudation, especially at the macula, or between it and the disc (Harlan). Even the stellate group of white spots in the macula formerly regarded as pathognomonic of albuminuric retinitis may be included among the retinal lesions connected with brain tumor (de Schweinitz).

With very extensive retinal lesions one may say that in all probability the trouble is of renal-vascular origin. With a complete absence of them, one may say that violent optic neuritis is probably due to organic disease within the cranium, but the possibility of confusion should not be lost sight of. Bearing it in mind, examination of the urine will usually show to which class the case belongs.

Given then a case of optic neuritis that can be excluded from the class we have just considered, its existence indicates with great probability the presence of grave organic disease within the cranium. Further than this we can scarcely go. It will be impossible to say from examination of the eyes that the cause is a brain tumor, a meningitis, or a cerebral abscess. The rapidity with which the neuritis runs its course will, however, in some cases give a valuable indication. Although Gowers shows that chronic neuritis never results from a rapidly growing tumor, in a tumor of very slow development the neuritis may be rather more chronic than from any other cause, slowly increasing for many months before vision is seriously impaired and running a course of years before it ends in atrophy.

OPTIC ATROPHY.

This is usually consecutive, coming on as the termination of optic neuritis. As such it has the same significance, and requires the same caution in excluding other possible causes.

Among 40, that I regarded as cases of consecutive atrophy, 13 were apparently due to organic intracranial disease; of these 3 were probably cases of tumor. The tendency in all cases is for optic neuritis to pass into atrophy, but in connection with brain tumor neuritis runs such a chronic course, that a large proportion of patients die before the atrophy predominates. The rapidity of the change to atrophy is usually related to the rapidity of the development of the neuritis. Marked permanent impairment of central vision and contraction of the field of vision are associated rather with the atrophy than with the neuritis. For a considerable time after atrophy is well-marked the evidences of previous neuritis remain unmistakable and not easy to overlook. But if the case be very chronic it is possible that the appearances which characterize the atrophy as consecutive, may be so trifling as to readily escape notice. These appearances are at first the remaining symptoms of neuritis; especially the swelling, now growing pale, the opacity which hides the disc outline, and the patches of exudate in the retina. Later the head of the optic nerve becomes clearly outlined, although still so opaque that the vessels can not be traced far into it. The vessels diminish in size, the veins as well as the arteries, though the former remain relatively large as compared with the latter: the vessel walls are more noticeable than normal, the vessel being sometimes accompanied by white streaks well out into the periphery. Patches of former retinal exudate may now appear as white degeneration, or only as areas of disturbed retinal pigment.

Around the disc may almost always be noticed some disturbance and absorption of the choroid, which is apt to be greatest at the upper and lower margins of the disc. This location distinguishes it from the somewhat similar choroidal changes due to previous eye-strain, which are generally most pronounced at the temporal margin of the disc. In rare cases sim-

ple atrophy, that is, atrophy without previous neuritis, has occurred in the course of brain tumor. It is due to pressure upon the optic nerves, chiasm, or tracts, or to direct destruction of the optic radiations or centers. Having this origin it becomes of considerable localizing value.

CHANGES IN THE PUPIL.

With impairment of accommodation changes in the pupil may occur as effects of direct involvement of the nerve tracts concerned. Sudden temporary disturbances may occur here, as they occasionally do in other forms of chronic organic disease of the brain and cord; but they have no especial significance with regard to brain tumors. The Wernicke symptom or reaction, or want of reaction, of the pupil to light thrown upon the blind half of the retina has in a few cases great localizing value. It throws no light upon the nature of the lesion which produces it. In attempting to elicit this symptom, especially when the vision is greatly impaired and the field contracted in all directions, it is sometimes necessary to throw the light into the eye from a point not greatly removed from the visual axis. In this way contraction of the pupil to light may be obtained, when, if the light were simply let fall toward the periphery of the retina, the result would be entirely negative. Of course, the nearer the light is brought to the direction of the visual axis, the greater the care that must be observed to insure that the pupillary reaction is not brought about by light falling upon the macula. Where the field of vision is still wide and the pupil reacts strongly to light, care should be taken that the light does not reach the seeing half of the retina through the sclera covering it, in sufficient quantity to provoke the contraction of the pupil, when, from light falling on the blind half of the retina, no contraction would occur.

To guard against this source of error I commonly use the light as reflected from the ophthalmoscope mirror, which can be concentrated in a small area upon the face and then turned so as to fall upon only the front and blind side of the eye. For instance, suppose a case of right homonymous hemianopsia—the left half of each retina blind—the source of light being behind the patient, the ophthalmoscope is held to the patient's right, as compared with his visual axis. The light is properly concentrated upon the brow or the nose, and then the mirror turned so that the light area will fall upon the pupil and portion of the sclera to the left of it, the sclera to the right of the cornea remaining in darkness.

PARASES OF THE EXTRAOCULAR MUSCLES.

In connection with brain tumor these are chiefly of value in the matter of localization, and the exact significance of each of the forms of extraocular paralysis in this direction need not now be rehearsed. In a general way such lesions, due to brain tumor, are more slow in their onset, and are longer in reaching complete development than those due to other causes, even perhaps those due to nuclear degeneration. But not much importance should be attached to this, since in connection with brain tumor their development may be entirely sudden.

A subject that has not attracted the attention it should have, and which will probably profitably repay careful study, is that of paresis or transitory disturbances of the extraocular muscles, which occur as distant symptoms with brain tumor, as they do with other

forms of organic disease, and which may be one way that the new growth causes such symptoms as headache and dizziness. In some cases at least they arise early, having probably much the same origin and significance as the mental disturbance, and the tendency to forced positions of the limbs, or involuntary movements that are sometimes seen. They are at least worth studying with the Maddox rod, the tendencies to deviation of the visual axes being taken when the eyes are turned toward various parts of the visual field.

NYSTAGMUS.

Although rarely accompanying blindness from cataract or corneal opacity, nystagmus is encountered in a large proportion of all cases of blindness from disease of the central nervous system. It is generally present when complete blindness has existed for many months in the course of brain tumor; but its occurrence in connection with other intracranial lesions robs it of especial diagnostic importance. It is probably more common and appears earlier in tumor of the cerebellum. In a few cases it appears while there is still fair sight, generally in connection with other disorders of the extraocular muscles.

IMPAIRMENT OF VISION.

Impairment of central vision and limitation of the field of vision may be of importance in calling attention to the existence of serious organic disease. The exactness with which they can be estimated quantitatively, gives them value as indicating the progress of the case. In the large majority of cases, however, they depend upon the optic nerve lesion and indicate its progress rather than that of the original disease. In a few cases where the affection of sight is due to direct involvement of the visual tract the changes in the field of vision become of the highest significance as a localizing symptom. Transient impairments may occur as a distant symptom, having the same significance as the mental disturbances and hysteroid symptoms.

Impairment of color perception can not be regarded as of a special localizing value. As Holden has shown, it may be merely a more delicate indication of the injury to the visual conducting apparatus, before this injury has become sufficient to interfere with the perception of form.

THE STIGMATA OF NERVOUS SYPHILIS.

Presented to the Section on Neurology and Medical Jurisprudence, at the Forty-ninth Annual Meeting of the American Medical Association, held at Denver, Colo., June 7-10, 1898.

BY WILLIAM J. ROTHWELL, M.D.

PROFESSOR OF NEUROLOGY, GROSS MEDICAL COLLEGE,
DENVER, COLO.

Specific lesions of the nervous system produce localizing symptoms similar in character to those which result from non-specific lesions having the same anatomic seat. Partial epilepsy of gummatous origin or hemiplegia from syphilitic thrombosis of the central arteries has no distinguishing features, per se: associate symptoms alone reveal its real nature. To describe these characteristic symptoms and to emphasize their importance in the diagnosis of cerebral syphilis in particular, is the object of my paper. A brief reference to the salient pathologic features of specific nervous disease is essential for the better understanding of the subject.

It is well known that syphilitic inflammation affects primarily the blood-vessels and meninges of the neu-

axis. While no part of this extensive territory is exempt from specific invasion, the most vulnerable parts are the convexity of the hemispheres, especially in their anterior portion, and more frequently still the base of the brain from the chiasm to the annular protuberance, involving the apparent origin of the cranial nerves. In both the meninges and the blood-vessels these gummatous products occur in two different states of aggregation, the one focal, the other diffuse. In the pia-arachnoid they are generally circumscribed; in the dura, on the contrary, diffuse gummatous infiltration is the rule. In the arterial walls they are also found as plaques or patches resembling atheroma, or as extensive infiltrations of the tunica intima. Remarkable peculiarities of this tissue are its rapid growth, low vitality and the rapidity with which it undergoes retrogressive changes.

Since the meninges envelop every part of the encephalo-spinal axis, and the blood-vessels traverse all its conducting paths and functional centers, a great number and variety of symptoms are to be expected in a general infection like syphilis, with a special predilection for these tissues. The symptoms of specific involvement of the nerve centers are, therefore, apt to be not only multiple but multiform. The initial manifestation may be, indeed, single, but if the disease be left to pursue its own course, evidence of multiple lesions will soon appear. Thus a double hemiplegia with aphasia, depending as it must upon two foci of disease, points to a specific origin, while a right hemiplegia, with or without aphasia, being of necessity due to a single lesion, indicates a common source. Of like significance is the association of symptoms of involvement of the third cranial nerve on one side with hemiplegia of the opposite side. A very striking exception to the law of multiplicity of lesion is the isolated loss of the iritic reflex to light, which is considered by Gowers to be an important indication of cerebral syphilis.

We have already called attention to the fact that the morbid product of syphilitic inflammation, the so-called gummatous exudate, grows rapidly and as rapidly disappears. The symptoms depending upon such lesions must possess the same transitory character. And this is true of all disturbances resulting from the specific process itself. Paresis, aphasia, strabismus and hemianopsia (when not associated with hemiplegia) of acute onset and brief duration, point almost unerringly to the primary effects of gummatous exudations. We must recollect, however, that these products may damage the nerve structures by pressure or by interference with their blood-supply, and that these secondary lesions belong in the class of necroses or degenerations, of which the effects may not be transitory but permanent.

Syphilitic arteritis is a curable malady, but when arterial thrombosis occurs with consequent ischemia and necrosis of that vascular area, the pathologic process is no longer specific, and the clinical history merges into that of common lesions, the disability becomes more or less permanent. Gummatous exudates, compared with other new formations, develop rapidly, and this pathologic feature gives to many specific lesions a characteristic onset. Cerebral hemiplegia of common origin has, as a rule, a sudden onset. Gowers claims that a sudden onset is characteristic of all vascular paralysis. When, however, the hemiplegia depends upon syphilitic thrombosis the onset is rather subacute than sudden. It is preceded by headache in

three-fourths of the cases according to Fournier. Other prodromic symptoms, such as brief spells of partial unconsciousness, transient aphasia, motor weakness on the side afterward paralyzed, are often observed. Fournier observed six cases of hemiplegia from this cause in which the muscular weakness slowly increased from day to day, the hemiplegia being the terminal stage of the process.

Ischemia, from narrowing of the lumen of the diseased artery and necrosis following its complete occlusion, necessitates a subacute onset. Exceptionally, however, a sudden and even fatal apoplexy occurs in specific arterial disease, but such sudden fatalities are caused by rupture of an aneurysm of one of the large vessels at the base of the brain. Again, syphilitic granulation tissue undergoes rapid absorption, and if uninfluenced by treatment is soon reproduced. As a result of this pathologic character the symptoms depending upon the presence of such exudates have a characteristically irregular course. A disease which pursues a uniformly progressive course is, in all probability, not due to a specific process. In this respect we may compare the course of syphilitic dementia with that of progressive paresis. The symptomatology has many points in common, but the course of the two diseases is quite different. Dercum, in differentiating these mental affections, makes the following point relative to syphilitic dementia:

"Even when the mental symptoms have been established they may suddenly recede and marked improvement may take place, to be followed, after an irregular interval of time, by a renewed accession of symptoms. On the other hand, spontaneous arrest and disappearance of certain symptoms may occur, together with the sudden appearance of others entirely new." What is here stated in regard to dementia is equally true of many somatic lesions.

Recurrent vesical disturbance of temporary duration, especially weakness of the detrusor muscle, is exceedingly valuable in the diagnosis of specific disease of the spinal cord. The clinical history of irritation or pressure affecting the cranial nerves often manifests the same irregularity. Gowers calls attention to a relapsing palsy of the third nerve. The well-known variations in the extent of the visual fields and the alterations in the pupillary reaction to light under varying degrees of pressure in the second and third nerves, respectively, are instances of the same irregularity in the evolution of specific diseases of the nervous system.

Headache is another very important stigma of cerebral syphilis. As before stated, it is present in three-fourths of the cases. Dangerous complications seldom occur without this prodromic symptom. It may be truly said that syphilis, like the rattlesnake, seldom strikes without warning. This headache is intense, generally referred to the depth of the brain, an encephalalgia. It is seldom diffuse, but localized in a definite region. When seated in the parieto-frontal region it is either unilateral or predominates on one side. One of the special characteristics of this headache is the regular exacerbations followed by remissions or intermissions to which it is subject. Absent, or quite supportable in the daytime, it reappears or becomes intensified in the early part of the night, and subsides gradually toward morning. Exceptionally, its maximum intensity is in the morning at the waking hour. Very seldom, indeed, does it persist night and day without any variation. This headache is

often accompanied by an evident change in the mental condition of the patient. In mild cases there may be only slowness of thought and inaptitude for sustained mental effort. In more pronounced cases there are veritable mental torpor, amnesia and a noticeable change of character. These prodromes acquire a still more precise signification when there are added to them formication and numbness of the extremities with transient or enduring pains.

Disturbances of sleep are also important stigmata of brain syphilis. Insomnia may be due to cerebral irritation, the result of initial organic changes in the blood-vessels or meninges. In other cases it is dependent upon the severity of the headache. The brain cells must be normally nourished to enjoy repose. The circulatory disturbances incident to specific changes in the brain tissue interfere with cellular nutrition, producing a state of irritable weakness and resulting wakefulness. Insomnia belongs, therefore, among the early manifestations of the disease. Like the other symptoms to which reference has been made, its diagnostic value is derived from association. Grey claims that both insomnia and headache cease on the supervention of paralytic or convulsive phenomena. In two cases of syphilitic hemiplegia recently observed by me, they were greatly, but not completely, relieved. Somnolency is a threatening prodrome of the cerebral complications of syphilis. It varies in intensity from mere drowsiness to profound lethargy. It is usually preceded by a period of very violent headaches. The sufferer pays but little attention to his surroundings. His countenance is dull and expressionless. He has attacks of vertigo, partial loss of consciousness and transient aphasia. He is usually compelled to keep his bed, sunk in almost continual sleep. At night there are mental wanderings and muttering delirium, resembling those of typhoid fever. His groans and complaints plainly show the continuance of violent pains in his head. If, during this semi-comatose condition, symptoms of involvement of the third pair of cranial nerves develop, such as diplopia, strabismus, ptosis, etc., they are evidently dependent upon basal syphilitic meningitis. Absence of fever and a tendency to spontaneous recovery, notwithstanding these ominous symptoms, are additional elements of great diagnostic value. In the milder cases the patient may attend to business, but his executive ability is greatly impaired. His memory is poor. He is unable to concentrate attention upon the matter in hand, and often falls asleep at work, though the previous night may have been passed in deep and continual sleep.

Circulatory disturbance, the result of arterial disease, is evidently the causal factor in these cases. Accordingly, many such cases, if not early detected and properly treated, eventuate in thrombosis, softening and hemiplegia. The value of these stigmata in the diagnosis of the cerebral complications of nervous syphilis is well illustrated in the case of syphilitic epilepsy. It is of quite frequent occurrence. Heubner encountered it twenty times in twenty-six cases of cortical syphilis. The attacks may assume all the known forms of comitial disease, from the mere vertiges and momentary absences of *petit mal* to the convulsive attacks and psychic equivalents of *grand mal*. While the first attack may appear in apparently perfect health, it is usually preceded by the whole cortège of premonitory phenomena common to cerebral syphilis. Severe nocturnal headache is a very common precursor of

the initial paroxysm. The age at which it begins is likewise a valuable stigma. Essential epilepsy begins in early life. When, therefore, epilepsy makes its first appearance in middle life, it is in all possibility, of specific origin. Again, syphilitic epilepsy does not pursue the monotonous inexorable course of the common affection, but bears the stamp of irregularity. This irregularity is manifested by a gradual shortening of the intervals between the paroxysms, eventuating in a series of rapidly recurring attacks, coma and death. It never exists for any great length of time as an isolated affection. It bears the stamp of multiformity. There are soon associated with it various symptoms differing from those of the ordinary disease. Cortical paresis, at first transient and following the attacks, may become paralysis and persist indefinitely.

While there is some loss of memory in essential epilepsy, especially when it becomes chronic, in the specific disease memory is very greatly impaired, and in some cases complete amnesia is manifest from the very first attack. The symptoms of paresis or paralysis of the oculomotor nerves are often added to the combination. Double optic neuritis frequently co-exists, this being in itself characteristic, in that its course is more rapid than when dependent upon any other lesion, not excluding cerebellar tumors. These stigmata also render valuable aid in the differentiation of syphilitic from parietic dementia.

1. Headache is present in both affections, but has different characteristics in each. In specific dementia it is of the usual persistent, paroxysmal, nocturnal type, while in paresis, though a very few severe spells are common, they never occur in long-continued series.

2. Syphilitic dementia pursues a characteristically irregular course. Paralytic phenomena which belong to the final stage of paresis may even precede the mental degeneration of the specific malady. The course of mental decay in paresis is progressive, with but few exceptions, while that of specific dementia is variable. In the latter some symptoms may wholly disappear to be replaced by others of a very different nature. Great mental improvement may take place, the mind may clear up and lucid intervals of long duration supervene.

3. If in a doubtful case, ptosis, strabismus, aphasia, or other paralytic symptoms develop, and especially if it be short-lived, the diagnosis is rendered certain, for suddenness and brevity are the brands of the motor phenomena of cerebral syphilis.

To recapitulate: Syphilis of the nervous system usually manifests itself in middle life, its serious complications being preceded by headache, insomnia or somnolence. It has an acute or subacute onset, pursues an irregular or atypic course, presents a multiplicity or multiformity of phenomena—the distribution of the paralytic symptoms being quite erratic—and causes a very early and marked impairment of the mental faculties.

Anatomic Studies in Insane Asylums.—Nissl made an urgent plea at the German Congress of Alienists, in September, for co-operation in the exact study of the anatomic foundations of the psychiatry of the brain. He proposed that a certain accepted region of the cortex should be studied by his method on a large number of brains in the various establishments, which will further the cause of science much more than a few single brains exhaustively studied.—*Klin-therap. Woch.*, September 25.

THYROID EXTRACT.

SOME RESULTS OF ITS ADMINISTRATION ON THE RED AND WHITE CORPUSCLES AND HEMOGLOBIN IN CASES OF ANEMIA ASSOCIATED WITH MELANCHOLIA.

Presented to the Section on Neurology and Medical Jurisprudence, at the Forty-ninth Annual Meeting of the American Medical Association held at Denver, Colo., June 7-10, 1898.

BY SAMUEL BELL, M.D.

MEDICAL SUPERINTENDENT, UPPER PENINSULA (MICHIGAN) HOSPITAL FOR THE INSANE, NEWBERRY, MICH.

The field of thyroid therapy, in the light of our present knowledge, is quite limited; experimental data have accumulated during the last year indicating various results. The most favorable, also the most reliable, were given by Ewald of Berlin, in epileptic psychoses, acromegaly, rachitis and Basedow's disease, to the International Congress of Medicine at Weisbaden; also by Professor Bruns of Tübingen, on goiter of the follicular variety, as being affected in a certain and prompt manner; cretinism is reported on by Schmidt; tetany and acromegaly by Schultz of Bonn.

Since beginning a series of experiments in cases of anemia, accompanied, or preceded, by melancholia, I have also observed some recent results, some of which were very good, obtained by Dr. Babcock of the St. Lawrence State Hospital, New York, in a variety of selected cases of mania and melancholia. At the Upper Peninsula (Mich.) Hospital for the Insane nine cases were under treatment in the first series, seven females and two males, all suffering from some form of mental depression.

Blood examinations were made before treatment, weekly, during and afterward, consisting of the enumeration of the red and white corpuscles and the estimation of the percentage of hemoglobin in each case. The counts were made with the Thoma-Leitz instruments, also by centrifugalization; the percentage of hemoglobin was estimated by Fleischl's hemometer. In normal blood in adult life the average number of red cells per cm. is estimated at about five millions for men and four millions five hundred thousand for women. The normal number of white cells per cm. is seven thousand five hundred. In hemoglobin examinations 100 per cent is considered normal when using Fleischl's instrument.

Case 1.—A. K., female, age 27. Had been under treatment about three months, with very little, if any, noticeable improvement. Strong symptoms of passing into primary dementia were present. A selected diet, tonics, exercise and different forms of electricity were all utilized in her case, without any apparent improvement. She was pale and anemic, with a phlegmatic temperament, and was hallucinated. Liver and intestinal secretions inactive, complicated by constipation and mental inertia. Thyroid treatment was begun, giving one 5 gr. tablet three times a day; the dose was gradually increased until fifty grains were being taken daily. This treatment was continued for one month. The temperature and pulse were taken twice a day. During the first ten days of treatment the temperature fluctuated between 98 and 99.4 degrees. When the maximum treatment was given the temperature rose to 101 degrees, remaining there but one day, when it declined to normal, remaining there during the last week of treatment. Pulse at beginning numbered 62; on the second day 50; on the tenth 100; and during the remainder of the month ranged between 98 and 72, the latter when treatment stopped. Pulse increased in rapidity and volume as the temperature rose. When treatment was discontinued there did not appear to be either physical or mental improvement, and for this reason it was no longer continued; her weight now commenced to increase rather rapidly and in a month she gained seventeen and one-half pounds.

Blood examination.—Red cells were normal, or a little above, at beginning and remained so during treatment, until about one day before treatment was stopped, when they diminished about one million; they were about one-sixteenth normal size. Hemoglobin was below normal at beginning and increased about 10 per cent. during treatment; 90 per cent. at commencement, 81 third week and 77 at close. White cells were below normal at beginning, increased 3460 the first week, dropped during the fourth week, and at the close there was an average increase of 2760. In this case the red corpuscles diminished in both size and number, while the white, as also the hemoglobin, increased.

	Red corpuscles.		Leucocytes.	Hemoglobin.

Feb. 22.	4,544,000		5,400	70 per cent.
Mar. 1.	4,736,000		8,860	72 per cent.
Mar. 8.	4,560,000	3,696,000	8,660	75 per cent.
Mar. 16.	4,776,000	4,032,000	5,040	81 per cent.
Mar. 22.	4,704,000	4,368,000	8,160	77 per cent.

Case 2.—M. E., female, age 23. Profoundly depressed, with an anemic appearance. Small amount of adipose tissue. Had been under treatment for nearly five months, without any beneficial results. No physical disease present. When thyroid treatment was commenced the temperature was subnormal, 97 degrees; pulse 80, with cold extremities. Mental activity very sluggish. Second day after this treatment had begun, temperature increased 1 degree; on the tenth day it was 99 degrees, and remained there during treatment. Three 5 gr. tablets were given per diem, and the dose gradually increased until 35 grains were being taken daily. The temperature reached its highest point when 25 grains were being taken. The pulse in this case did not vary much with the change in temperature; during the last week of treatment it ranged from 100 to 116, being a difference of from 20 to 36 at the commencement of treatment, while the temperature remained normal or below. This case was both stuporous and stubborn, was affected rapidly, even by small doses. The cold extremities and surface generally was changed, the blood filling the superficial capillaries and continued so, with some improvement in mental activity, which lasted during treatment; no permanent improvement followed. This patient had received, prior to being admitted at the Upper Peninsula Hospital, a very severe burn, which necessitated amputation of arm at shoulder and subsequently quite extensive skin grafting. During the thyroid medication the old wound, which had almost healed, took on an irritative condition, retarding granulation quite seriously. Physical condition did not change, although she now shows a gain of five pounds in weight.

Blood examination.—The red corpuscles were small and above normal in number from the beginning of treatment until the close, about five million per cm. Leucocytes numbered 8330 at commencement and 5250 at close, showing a diminution of 3080. Sixty-seven per cent. of hemoglobin at beginning increased to 85 during the first week, second week 77, third 82 and fell to 64 at close of treatment, being lower than when treatment was begun. This case differs from the others in that the amount of hemoglobin was reduced, also the number of white corpuscles, while the red cells were not perceptibly influenced.

	Red corpuscles.		Leucocytes.	Hemoglobin.

Feb. 24.	5,072,000		8,330	67 per cent.
Mar. 2.	5,528,000		7,650	85 per cent.
Mar. 9.	4,992,000	4,516,000	6,940	77 per cent.
Mar. 16.	5,032,000	4,312,000	8,350	82 per cent.
Mar. 23.	5,956,000	3,696,000	5,250	64 per cent.

Case 3.—H. G., male, age 30. Treatment begun with 15 grains and increased to 45 per diem. Before beginning treatment temperature was 97 degrees; on the third day 98; on the sixteenth 99.4, the highest point reached during treatment, dropping again to 98 and remaining there during the remainder of treatment. Pulse, 72 at beginning, increased to 100 and dropping again to 80 when treatment ceased. This case was of more than ordinary interest; a young man of good family became depressed and attempted suicide by cutting his throat with a meat ax. After being received at the hospital, he was placed on appropriate treatment, such as tonics, exercise, gymnastics, games, etc., everything with a view to the removal of the cloud from his mental horizon. His case did not yield to this line of treatment; periodic depressed spells were becoming prolonged. At this time he was placed on thyroids. After two weeks' treatment, temperature began to increase, and *pari passu* the mental depression began to give place to a brighter, more cheerful and observing condition; so marked was the change in his general appearance that his friends, in visiting him, observed the improvement. No relapse has occurred and

the periods of mental depression which were quite frequent before, have entirely disappeared. Patient was discharged, in every way much improved and, to all appearances, entirely recovered. His physical condition was a great deal better, having gained twenty pounds.

Blood examination.—Red cells were found to be normal, or slightly below, both in number and size; at commencement numbered 4,728,000, and about the same at the close. The leucocytes were below normal at commencement of treatment (5900) and at the close numbered 8,230, being an increase of 2330. Ninety-one per cent. of hemoglobin at beginning and 94 at the close. This case showed a marked increase in the white corpuscles and a 3 per cent. increase in the hemoglobin, while the character and number of the red cells were not materially changed.

Feb. 26.	4,728,000		5,900	91 per cent.
Mar. 3.	5,096,000		6,280	90 per cent.
Mar. 10.	4,680,000	4,704,000	8,500	85 per cent.
Mar. 17.	4,784,000	4,256,000	8,230	94 per cent.

Case 4.—L. B., female, age 36. Under thyroid treatment one month, commenced with 15 grains and increased to 30 per diem. Temperature 98.5 when first dose was given; four days later was subnormal; on the tenth day rose to 99.4, the highest during treatment, and then ranged from 98 to 99 during balance. The pulse was slow at first, and remained so during the greater part of treatment, except during the last few days, when it ran up to 110 and 112. This patient's intellect was not very well developed; had given illegal birth to a child. Was anemic and did not respond to chalybeate and other adjuncts for the building up of the mental and physical condition. She suffered from melancholia agitata and did not improve, either physically or mentally, as the result of this treatment. It is now four months since the treatment ended, but the same fixed delusions and hypochondriacal condition remains. Her weight fluctuated and is now a little below what it was when treatment was discontinued. No blood examination was made in this case.

Case 5.—L. H., female, age 33. Mother of four children. Suffering from a mild form of melancholia with hallucinations. Had been under treatment in the institution about eight months before beginning with the thyroids, without any benefit. Commenced with the usual dose and increased to 25 grains daily. Temperature increased about 1 degree almost immediately, and at the end of thirteen days reached 101.2 degrees, declining gradually to normal and not rising again during remainder of treatment. Circulation increased gradually in conjunction with the temperature: when the latter was highest the pulse was 100, showing an addition of 40 beats, it being but 60 at commencement. At the close of treatment, there was no improvement, either mental or physical; indeed the depression seemed to be more profound and a more anxious appearance generally. Treatment was ended on December 22, and she was then placed on general tonics, together with electricity similar to that which had been given her prior to the thyroid treatment. Her weight now began to increase: during the first month gaining ten pounds; the second month eight pounds, and on the 23d of the third month, when she was discharged cured, her weight showed an increase of twenty-two and one-half pounds. A dense mental cloud which seemed to hang over her less than three months before, and seemed to be deepening, after this treatment gave way to a brighter, happier, more cheerful and appreciative responsive condition, which can only be appreciated thoroughly by her family, friends and those having her welfare at heart. No blood examination was made.

Case 6.—E. S., female, age 25. Mother of two children. Depressed. Had been considered mentally unbalanced for upward of four years before being received at the Upper Peninsula Hospital. Had made an attempt to destroy her two year old child by burning. Began taking 18 grains of thyroid daily, and increased to 27 grains in two weeks. Temperature was 97.4 at beginning; on the third day increased two degrees, and remained at 99.4 during the balance of treatment, with the exception of a brief interval, when it declined to about normal, but immediately rising again. Examination of the urine revealed, at first, traces of albumin, with very few pus corpuscles, urea normal, 2.8 per cent.; at the close of treatment, pus corpuscles had increased, specific gravity increased from 1012 to 1026. Pulse had increased from 66 to 116. Two weeks after treatment ceased her weight had increased six and a half pounds.

Blood examination.—The red blood cells were reduced, also the hemoglobin, the latter 11 per cent., and the white cells increased about one thousand.

	Thoma-Leitz.	Centrifuge.	Thoma-Leitz.	
Mar. 12	5,072,000	4,704,000	7,540	94 per cent.
Mar. 19	4,884,000	4,704,000	7,690	90 per cent.
Mar. 28	5,040,000	4,368,000	7,640	80 per cent.
Apr. 2	5,176,000	3,696,000	6,950	82 per cent.
Apr. 8	4,364,400	4,368,000	7,030	83 per cent.
Apr. 15	4,704,000	4,256,000	8,850	80 per cent.

Case 7.—E. A. C., female, age 45. Suffering from melancholia, with delusions. Would sit in the hall without apparently observing any object or person, from day to day. Suffered from hemicrania. Began by taking 16 grains and increased to 35. Temperature was normal at beginning, and was not increased throughout treatment, but decreased, being 97 degrees at the end of thyroid medication. Circulation was much more affected than the bodily heat, increasing from 74 to 120 per minute during the first ten days of treatment. Urinal examination showed pus corpuscles, epithelium and traces of albumin present throughout treatment; specific gravity 1018; urea 1.2 per cent. Weight remained practically the same during treatment, also after.

Blood examination.—In this case the red blood corpuscles were slightly decreased and the white increased, the latter about two thousand. Hemoglobin remained substantially the same.

	Red Corpuscles.		Leucocytes.	Hemoglobin.
	Thoma-Leitz.	Centrifuge.	Thoma-Leitz.	
Mar. 26	4,448,000	4,368,000	5,160	80 per cent.
Apr. 3	4,061,600	4,256,000	6,400	82 per cent.
Apr. 8	5,088,000	4,480,000	6,950	82 per cent.
Apr. 15	4,401,600	3,696,000	7,000	80 per cent.

Mental influence.—In the last two cases there was a marked change: a despondent and forlorn appearance has given place to a brighter and more cheerful condition.

Case 8.—P. F., male, age 44. Suffering from stuporous melancholia. Began treatment with 15 grains per diem and increased to 30. Temperature was immediately affected, increasing from 98 to 101 on the third day after treatment had commenced. On the sixteenth day it rose to 102, declining to 101, and remaining there during balance of treatment. Pulse was not influenced so much as the bodily heat, not varying more than twenty beats. Notwithstanding the temperature was markedly influenced there was no improvement in the mental activity. Pus as well as blood corpuscles and traces of albumin and epithelium were present in his urine. In this case the bodily weight was not changed to any appreciable extent.

Blood examination.—The white cells, numerically, were not changed; the red cells were slightly diminished, while the hemoglobin was reduced 14 per cent.

	Red Corpuscles.		Leucocytes.	Hemoglobin.
	Thoma-Leitz.	Centrifuge.	Thoma-Leitz.	
Mar. 28	4,548,000	4,592,000	6,850	79 per cent.
Apr. 4	4,184,000	4,144,000	7,570	76 per cent.
Apr. 11	3,700,000	4,592,000	6,660	75 per cent.
Apr. 18	4,208,000	4,480,000	6,500	65 per cent.

Case 9.—E. B., female, age 44. Mother of four children. Suffering from melancholia gravis or hypo-melancholia; great mental anxiety. Impairment of motion and inhibition, which dated back about one year from the death of her husband, who was killed by an accident in a mine. There was an entire suppression of the menstrual molimen. Every remedy, therapeutic and otherwise, was exhausted in her behalf, without permanent benefit. She began taking one 5-grain tablet three times a day on March 26, 1898; on the fourth day after beginning treatment the temperature dropped to 97 degrees. Twenty grains were given; the system seemed profoundly impressed; the temperature rose to normal, dropping again to subnormal, treatment was relinquished on the eleventh day on account of the increasing exhaustion. The pulse and respiration were increased slightly. The systolic cardiac impulse very much decreased. Lost eleven pounds in weight during the eleven days of treatment. No improvement in mental or physical condition either during treatment or since it has ceased.

Blood examination.—Red corpuscles increased 728,400; leucocytes 1,330, and hemoglobin 7 per cent.

Mar. 25	3,624,000	4,144,000	5,200	70 per cent.
Apr. 2	4,362,400	4,368,000	6,530	77 per cent.

THE THERAPY AND THEORY OF ACTION.

There are, according to some very reliable authorities, two main theories advanced. The first is the auto-infection theory—the gland having for its func-

tion the destruction of the natural toxins; without the latter we have the condition known as myxedema. The second is the internal secretion theory—the thyroid being considered as a secreting organ. The secretion is taken up by the lymph vessels and is necessary for the proper metabolism of the body, especially for nervous and connective tissue. According to either of these theories, the administration of the dessicated gland supplies the lacking secretion, which may be some chemic substance that is necessary to health or even life. Ewald, in a pithy sentence, states that the gland acts as an antitoxin against certain elements that appear as by-products of tissue change. The exact constituents of this substance have never been definitely made known. An organic iodine compound from the sheep thyroid has been extracted, called thyro-iodine, and in the present state of our knowledge the weight of authority is in favor of this being the effective chemic agent in thyroid therapy.

The rationale of this treatment is not very clear. It may be of great value in mental diseases as a method of diagnosis, but it is difficult to comprehend just how this treatment could improve a case where degenerative changes have taken place in the cell structures. Based on the theory of auto-infection, frequently cases have occurred where malaria, typhus and pleurisy are capable of developing in the blood antitoxins that have resulted in curing cases of mental disease. It is not unreasonable to suppose that in cases of mental alienation due, it may be, to some toxin, rather than to a lesion of the brain, the action of the thyroid is to promote metabolism. This being the case, the utility of thyroid therapy is obvious. In the series of cases treated by me, I have observed that those who were not benefited are developing symptoms of organic disease and passing into a condition of chronic dementia, while in those who were improved, it is a reasonable deduction, on the antitoxin theory, that the condition was functional, and that cellular disorganization had not taken place. Nine cases received the thyroid medication and were under close medical supervision; in five cases there was a marked change for the better, the other four were not, so far as we could observe, favorably influenced, physically or mentally, either during the treatment or since. Three of the five who were improved began to increase in weight during the treatment, and two of them did not until after treatment was relinquished. The psychologic effect was observed almost from the beginning of treatment in those who were permanently improved.

It was noticeable that the minimum dose would produce a systemic effect in some more rapidly than a maximum dose in others. Every case requires close observation and the dose graduated in accordance with the effect produced upon the nerve centers and circulation, or in other words, every case must be a law unto itself. Fifteen grains per diem was the maximum dose to begin with, in some gradually increased to fifty in accordance with indications.

The Modern Magazine.—Managing Editor—"How many pages have you?" Foreman—"Two hundred and twenty-four." Managing Editor—"Two hundred and twenty-four! That would be too bulky. How is it proportioned?" Foreman—"One hundred and ninety pages of advertising and thirty-four pages of reading matter." Managing Editor—"Bring me the proofs of the reading matter. We will have to cut down to 200 pages."—*Ohio State Journal.*

ACUTE MENINGITIS.

OBSERVATIONS ON DIFFERENTIAL DIAGNOSIS AND TREATMENT.

Presented to the Section on Neurology and Medical Jurisprudence, at the Forty-ninth Annual Meeting of the American Medical Association, held at Denver, Colo., June 7-10, 1898.

BY DANIEL ROBERTS BROWER, A.M., M.D., LL.D.

Professor of Mental Diseases, Materia Medica and Therapeutics, Rush Medical College, Chicago University; Professor of Diseases of the Nervous System, Women's Medical School, Northwestern University; Professor of Diseases of the Nervous System, Post-Graduate Medical School.

CHICAGO, ILL.

The differential diagnosis of the various forms of meningitis is, in my experience, often impossible. There are, however, two methods of certain diagnosis, when available. One is by lumbar puncture of the spinal cord, as recommended by Quinke and Ziemssen, and the bacteriologic examination of the withdrawn fluid to determine the micro-organisms which are present, and the other depends on the Skeer sign, described by me in a clinical lecture published in the JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION, Jan. 7, 1888, and by Dr. Skeer of Chicago twenty years before. The Skeer sign when present will enable a diagnosis of

tubercular meningitis to be made very early. It is due to the deposition of tubercle around the pupillary margin of the iris. It shows itself first as a distant wreath of white clouds about a millimeter from the margin (see Fig. 1). This sign occurs before any change has taken place in the size of the pupillary orifice. After three or four days these minute cloud-like masses disappear and a yellowish-brown circle takes their place. (see Fig. 2), becoming more and more attenuated as the pupil dilates. These secondary changes are doubtless due to degeneration of blood-vessels from the tubercular deposits. Unfortunately, this sign is frequently absent, but when present is pathognomonic of tubercular meningitis.

The treatment of the various forms of acute meningitis is very unsatisfactory, as you all well know, not only because of the almost constantly present nausea and vomiting, but also because of the very high mor-

talidity. The difficulty of medicating by the mouth led me to adopt, some fifteen years ago, the method of inunction; first with mercury without any success, and then iodoform with some success. I prefer to use the 10 per cent. ointment of iodoform and lanolin, believing that lanolin favors the absorption of the iodoform, this to be applied daily to the shaven scalp. Absorption usually takes place promptly, as I have been enabled to detect the iodine in the urine and saliva one hour after the inunction. The amount absorbed can not be very great, as I have never seen the untoward effects that sometimes follow the use of iodoform in open wounds. I have used in the treatment of a single case as much as 10 grams of iodoform.

The following list of cases was seen in consultation with Chicago physicians from time to time and the results of treatment have been obtained from their statements:

	No. cases.	Recov-eries.	Deaths
Dr. J. S. Hunt (deceased)	8	6	2
Dr. J. W. Fitzmaurice, 2876 Archer Ave.	6	4	2
Dr. P. H. Conley, 477 Grand Ave.	2	2	0
Dr. M. L. Loevenson, 523 S. Jefferson St.	2	1	1
Dr. W. D. Neel, 329 W. Erie St.	10	6	4
Dr. David O'Shea, 109 W. 21st St.	7	6	1
Dr. Wm. Martin, 100 State St.	2	1	1
Dr. G. W. Reynolds, 1924 Arlington Pl.	3	3	0
Dr. D. R. Brower, 34 Washington St.	5	3	2
Total.	45	32	13

In one of the cases that died in the practice of J. S. Hunt, and in one of the cases I have reported as terminating fatally, the Skeer sign was present, making the cases tubercular meningitis. In the other fatal case I have reported, lumbar puncture determined the bacillus tuberculosis to be present.

The following letter was received from Dr. George W. Reynolds:

You asked me to write up the histories of the three cases of cerebral meningitis which you saw with me in consultation. Those cases date back a number of years, and no records of them are now in my possession, although the patients' histories, diagnoses and treatment are still vivid in my recollection. I can remember that after all methods of treatment had been tried and no improvement and death seemed inevitable, you suggested shaving the head and rubbing into the scalp a 10 per cent. inunction of iodoform daily. This treatment was continued daily until marked improvement was evident, after which the frequency of dosage was lengthened to two or more days until the patient was convalescent. In the first case, a child of 2 years, with all the characteristic symptoms of cerebral meningitis well pronounced, who had been ill two or three weeks before you saw him. At that time he was comatose, the fontanelle was open wide and the brain pulsations could be distinctly felt. High temperature and general symptoms indicating a serious cerebral meningitis, with a very grave prognosis. After a week or ten days of the iodoform treatment a marked improvement manifested itself, and the same line of treatment was pursued, but less frequently, until the child appeared perfectly well and was discharged cured. I saw the patient a few days ago, now a boy 12 years of age, and was informed by his father and mother that he was bright and well up in his studies at school. The other two cases I have been unable to locate, although I have tried to do so, consequently my delay in sending you these notes. However, I can assure you that they recovered and were under my observation for one or two years after they were treated by the same method, and were, to all appearances, well. Yours very truly,

G. W. REYNOLDS, M.D.

This communication is presented to the Neurological Section for the purpose of provoking a discussion on the two important topics indicated in the title, hoping to add something to our fund of knowledge in these important matters.

DISEASES OF NERVES REQUIRING SURGICAL TREATMENT.

Presented to the Section on Neurology and Medical Jurisprudence, at the Forty-ninth Annual Meeting of the American Medical Association, held at Denver, Colo., June 7-10, 1898.

BY J. HERBERT AUSTIN, M.D., M.R.C.S., ENG.

CLINICAL SURGICAL ASSISTANT UNIVERSITY MEDICAL COLLEGE,
KANSAS CITY, MO.

I appear before you, gentlemen, not as a neurologist but as a general surgeon. No specialty is entirely isolated. The work of any of us should interest us more or less. The best specialist is he who is well posted on subjects besides those in his own particular line of work.

The nervous system is the most wonderful system in the human body, connecting together, as it does, in some mysterious manner the mental and the physical. It has complete control of the physical, governing all our movements, both voluntary and involuntary. It depends largely upon the site of the lesion in the nervous system as to how grave will be the damage resulting. If in a terminal nerve, such as the ulnar, the parts supplied by it are rendered powerless and motionless; while an injury of the cervical region of the spinal cord reduces the body in an instant to a state of inaction, indifference and paralysis.

From what has already been said it will be seen that the treatment of disease and injury of the nervous system in so far as it interests the surgeon, affords an immense field for further study and research. This study is rendered further interesting from the fact that there is no system in the human body where recuperation takes place to such a marked extent. I am sure that it is a great pleasure to us all to note the very great advances that have been made in surgery of the nervous system within the past few years, so that cases are now successfully treated which but a few years ago would have been regarded as beyond human aid.

In considering the surgery of the nervous system we at once see that it is, of necessity, divided into three parts, namely: 1, surgery of the brain; 2, surgery of the spinal cord; 3, surgery of the nerves. In the third division we find two subdivisions: *a*, injuries to nerves, such as contusions, strains, compressions, rupture or laceration, puncture, division, foreign bodies in nerves; *b*, diseases of nerves requiring surgical treatment.

This is the portion of the surgery of the nervous system that I wish to touch on. There are seven under this heading that attract our attention: they are sciatica, neuralgia, muscular tic, traumatic paralysis, traumatic neuritis, new growths and tetanus.

SCIATICA.

This affection is often called a neuralgia, but it is in reality generally a neuritis or a peri-neuritis. There are two forms: primary, which is generally of idiopathic origin and usually a neuritis; secondary, which follows some affection of the pelvis, spinal cord or hip-joint and is often a neuralgia. The more common causes are exposure to cold or damp, especially after severe muscular exertion, and the pressure of pelvic tumor on the nerves. Various constitutional conditions, such as gout, rheumatism, syphilis and anemia, are often present. About four males suffer from this disease to one female.

Morbid anatomy.—As stated above it is generally a neuritis; the nerve is red and swollen but the nerve fibers are not often destroyed.

Symptoms.—Pain of a shooting character, which passes down the nerve, is the principal one. The pain is due to the implication of the nervi nervorum. The pain is always increased by any movement. Some spots, usually at the notch and in the middle of the thigh, are more sensitive than others, and become exquisitely painful on pressure. The neuritis in rare instances ascends and involves the cord. Wasting of the muscles occurs in protracted cases, but the reaction of degeneration can seldom if ever be obtained. The duration as well as the severity varies very much, but as a rule it is an obstinate affection, lasting for months, or even, with slight remissions, for years. Relapses are common, and the disease may be relieved in one nerve only to appear in another.

Diagnosis.—Determine whether the disease is primary or secondary to some affection of the pelvis, spinal cord or hip-joint. Affections of the hip-joint can be easily distinguished by the absence of tenderness in the course of the nerve and the pain caused by movement of the hip-joint or by pressure in the region of the trochanter. If sciatica exists, and the hip-joint be sound, then the movements of the joint are free and unaccompanied by pain, unless flexion is carried far enough to render the nerve tense. A careful rectal examination should be made, and in women pelvic tumor should be excluded. Careful examination will usually distinguish between sacro-iliac disease and sciatica. Pressure on the nerve trunks of the cauda equina as a rule causes bilateral pain and disturbance of sensation, and as double sciatica is rare, these symptoms always suggest lesions of the nerve roots. Clearly defined differences usually exist between the severe, lightning pain of tabes and the pain of sciatica.

Treatment.—The internal treatment depends on the case, i.e., whether there are any constitutional conditions existing which require attention. Absolute rest in bed from three to five weeks, fixing the leg on a splint to have as little tension on the nerve as possible, has proved to be especially useful. Osler recommends hydrotherapy, especially the warm baths or mud baths. He states that many severe cases are much relieved by a prolonged residence at one of the thermal springs. In severe cases local applications are often useful. Cold may be applied by means of ice, coil, etc. Counter-irritation, if desired, may be employed by means of a thermocautery or by blisters along the sciatic nerve. Massage is useful; press deeply down and draw the nerve away from the cord. Where the pain is extremely severe, deep injections into the nerve of cocaine or eucain, $\frac{1}{8}$ or $\frac{1}{4}$ grain, will give great relief. Morphin, on account of its being such a dangerous remedy in sciatica, because of the great risk there is of the morphin habit being contracted, should be withheld as long as possible, and only when the pain is really unbearable. Never allow a patient to use a hypodermic needle. If milder measures fail then operative procedures should be tried. These are either acupuncture or nerve-stretching. Acupuncture is performed as follows: The patient is laid on his face and any tender spots located by pressure. The nerve should now be punctured by several needles. This will cause a sudden, sharp pain to shoot down the thigh. These needles, which should not be more than a half dozen in number, after being left in for a few moments, are removed and a permanent cure results.

Nerve-stretching.—There seems to be some differ-

ence of opinion as regards the value of this operation in sciatica. Dr. Weir Mitchell states that he never yet met a case where nerve-stretching was necessary, while Erichsen says that this operation has been more successful in sciatica than any other painful affection for which it has been undertaken. This operation was originally introduced by Nussbaum as a mode of treating intense neuralgia following injury. But to Marshall belongs the honor of having first suggested its use for neuritis. He was first to conclude that nerve trunks must contain sensory fibers, distributed in their sheaths, i.e. the *nervi nervorum*. Since that Victor Horsely has clearly shown that medullated fibers terminating in tactile corpuscles exist in the perinsurium and epiceurium of all nerves. From this fact, then, we may conclude that the pain and tenderness of the nerves in neuritis is explained by the pressure upon the *nervi nervorum* and new connective tissue. Now, since in stretching a nerve the strain is first brought to bear on the sheath in which the *nervi nervorum* ramify it is easy to understand that they may be stretched or torn to such an extent as to destroy their conducting power, and thus render the nerve insensible without preventing its transmitting sensory and motor impulses through its proper tubules. It is more convenient to make the incision about the middle of the back of the thigh than at the lower border of the *gluteus maximus*, because here the whole of the ham-string muscles must be drawn inward and the nerve sought for external to them. Expose the nerve by an incision parallel to its course, properly clean it from the surrounding tissues, and then raise it with a blunt hook on the forefinger. Stretch it both centrifugally and centripetally; maintain the traction for about five minutes. The force to be used varies with the size of the nerve. The surgeon must decide as to the force to be used in each separate case. Experiments go to show that the breaking strain of a healthy sciatic nerve is never under eighty pounds.

NEURALGIAS.

These are nerve pains which may or may not be due to organic lesion; to functional disturbance of the central or peripheral extremities of the nerve or to neuritis in the course of the nerve. Neuralgia may occur in almost any part of the body, but is most frequently found in the division of the fifth pair of nerves. In some cases the whole or part of an organ may be affected, while in others one of the larger joints is the seat of very severe suffering. In a third class of cases the extreme cutaneous sensibility is the most marked symptom, the patient wincing and suffering severely whenever touched, however lightly.

Etiology.—The causes of neuralgia are numerous. They may be either constitutional or local. There may be some source of irritation, or an abnormal condition of the ganglionic cells of the sensory nerves may exist. Depressing influences of all kinds are very apt to produce it; and hysteric temperament may cause a spinal and articular form, while various peripheral irritations give rise to some of the more obscure forms of neuralgia. Among the causes may be mentioned exposure to cold, pressure on the nerve, toxic influences, overwork, and various constitutional conditions, such as rheumatism, general debility, anemia, etc. Neuralgia occurs oftener in association with anemia than any other constitutional condition, and this fact explains its frequency among females.

Symptoms.—Pain is the most important symptom. It is of a spontaneous nature; occurs in paroxysms; runs along the course of the nerve by the *nervi nervorum*, and is of a darting, burning character. These paroxysms, lasting from a few moments to some hours, may return at regular intervals. Certain tender points exist along the course of the nerve, usually where the nerve passes from a deeper to a more superficial position. These pains are supposed to be caused by sudden explosions in the ganglionic cells in the gray matter of the cerebrum, where all nerve fibers terminate. Other symptoms of neuralgia are numbness, transient hyperesthesia, vomiting, and various vasomotor disturbances.

Diagnosis.—This is usually easy. From organic disease of a part it can be distinguished by the presence of great superficial tenderness; by a hysteric temperament and by the absence of all the other symptoms of organic disease; from inflammation, by the intermittent nature of the pain, by its occurring in hysteric subjects, and by the absence of the constitutional symptoms of inflammation. When inflammation and neuralgia exist together the diagnosis may be difficult. Here the presence of superficial tenderness and a relief of the pain by deep pressure points to neuralgia, while in inflammation there is no tenderness of the surface, and on deep pressure the pain is extreme.

Treatment.—The treatment varies with the cause. If the cause can not be removed, the disease is incurable, although the suffering may be relieved by suitable means. If the patient's general health is poor, then the neuralgia will recur unless he is built up with tonics and general hygienic measures. For the pain, local applications of a sedative nature, such as opium, aconite, belladonna or chloroform, are often useful. Some of the newer remedies—antipyrin, phenacetin, or antifebrin—should be tried. These failing, then morphin may be tried, but with care, the patient never being allowed to use the hypodermic needle. Cocain, hypodermically, usually relieves the pain for a time. Acupuncture may be tried, or aquapuncture, i. e., the injection of distilled water beneath the skin. Freezing the part with ether spray often proves useful. The continuous electric current may be used, placing the positive sponge near the seat of pain, and with the negative gently rubbing the neuralgic spot until the skin is slightly reddened, and until it causes a slight tingling or burning, but not pain. In the most intractable cases the surgical means that may be tried are nerve-stretching or excision of a portion of the nerve. Of the two operations the latter is to be preferred, but too often the pain returns after it. In fact, the operation can only be of use when the pain is peripheral, due to some irritation existing between the part cut and the ends of the nerve. If the neuralgia depends upon any central cause, or if the irritation exists higher up than the point divided, the operation has always eventually failed, although at times a temporary cessation of pain for a few weeks has occurred.

MUSCULAR TIC.

Muscular tic, also known as "histrionic spasm," is an almost incessant twitching of the facial muscles. It often prevents sleep, and at all times causes great annoyance to the patient. As for its etiology, it is thought that some form of irritation of the facial nerve, the nature of which is yet unknown, acts as a

causative agent. At times this disease is associated with neuralgia of the fifth nerve. In the severer cases the nerve should be stretched. This operation when properly done, causes complete paralysis of the muscles of the face, which lasts a longer or shorter period, according to the force used in stretching. As the nerve recovers its function, however, there is always more or less return of the twitching, so that this operation must be looked upon as a relieving agent merely, and not as a curative one. The operation may be performed as follows: Make a curved incision just behind the ear from the root of the mastoid process to about the level of the angle of the jaw. Next, carefully clean the anterior border of the mastoid process and the edge of the tendon of insertion of the sterno-mastoid muscle. Now turn the parotid gland forward. Crossing the wound at about right angles will be seen the border of the digastric muscle, and parallel to it the nerve emerging from the middle of that part of the mastoid process which is exposed. As the internal jugular vein is in close proximity, great care must be used in cleaning the nerve; when once clear it should be firmly stretched with two blunt hooks.

TRAUMATIC PARALYSIS.

This may be brought on by one of three causes: Injury of brain, injury of cord, or injury of nerves. When due to cerebral injury it may vary from a localized paralysis to a hemiplegia. When due to injury of the cord it varies from a mere impairment of sensation and motion to complete paraplegia, with loss of sensation in the paralyzed parts.

Treatment.—If possible remove the cause of the paralysis, e. g., pressure on the brain or cord, and a complete recovery often may be speedily brought about. In treating any paralysis, we should, if possible, restore the muscles to their usual activity as soon as can be. The tendency to atrophic and other changes should be counteracted. Always see that a paralyzed part is warmly clothed, kept clean and not unduly pressed upon. Passive motion of joints along with attempts at voluntary movements proves very beneficial. Electricity, however, gives the best results in paralysis. It increases the vascularity of a part; improves the nutrition of muscles, nerves and other structures; prevents, retards or removes spasmodic contractions, and it seems that the long-continued use of electricity improves the nutrition of the part of the nerve-center from which the nerve or nerves which supply the affected muscles originate, thus restoring the function of a muscle or nerve when its activity is impaired and thereby bringing about restoration of voluntary movements.

TRAUMATIC NEURITIS.

This may be a result of any injury of a nerve, but generally arises from bruises or strains and is sometimes connected with gout or rheumatism. It is rarely found in amputation stumps unless union has taken place by second intention with unhealthy inflammation and suppuration, thus pressing on the bulbous end of the nerve and causing great pain and muscular spasm. The disease is really a chronic inflammation slowly ascending the nerve, and extending in extreme cases to the cord, giving rise to sclerosis. The symptoms of traumatic neuritis are intense pain and tenderness in the line of the affected nerve. Usually there is weakness or paralysis of some of the muscles supplied, but in some cases there are spasms. There

may be an intense neuralgic pain in the parts supplied by the nerve in some cases; in others, there may be numbness, tingling or anesthesia.

Treatment.—The treatment consists of operative and non-operative measures, milder cases being treated without operation. The tender nerves should be freely blistered and the nerve kept at rest. Great relief is afforded in some cases by a long strip of capsicum plaster applied along the line of the nerve. Constitutional conditions must be treated by suitable remedies. Electricity in the earlier stages of the disease not only is of no use, but may do positive harm. In cases where all these milder efforts have failed, the operations which may be resorted to are three in number: 1, excision of the bulbous ends of the nerves; 2, division or excision of part of the affected nerve; 3, nerve-stretching.

1. *Excision of the bulbous ends of the nerves.*—In some cases where a painful stump is caused by the nerve being implicated in the cicatrix, relief may be given by this operation. In other cases, where the symptoms are due to chronic ascending neuritis, the operation, although giving relief for a time, must fail to produce a cure.

2. *Division or excision of portions of the nerve.*—The smaller nerves are often divided or partly excised in cases of persistent traumatic neuralgia, and as a last resort in extreme cases, portions of the larger nerve trunks have been excised. These operations in some cases give a perfect cure; in others only temporary relief. At times a section of the whole brachial plexus does good.

3. *Nerve-stretching.*—As stated while considering the treatment of sciatica, this operation acts beneficially by stretching the sheath in which the nervi nervorum ramify. This stretches or tears the nervi nervorum so as to render them insensible to pressure upon them of inflammatory exudations and new connective tissue.

NEUROMATA.

A neuroma is a tumor situated on a nerve. There are two classes of neuromata: the true, consisting of a nerve substance proper, and the false, made of fibrous tissue. A true neuroma is generally made up of nerve fibers only, or very occasionally of ganglion cells. A false neuroma, also a fibroma, is made up of white fibrous tissue, the nerve fibers, as a rule, being stretched over it, or passing along one side, very seldom being involved in the tumor mass proper. A fibroma which springs from the epineurium is by far the commonest form of neuroma. The tubercula dolorosa are small, painful, subcutaneous nodules. Some authorities consider these growths as true fascicular neuromata, while others look upon them as fibromata, and it seems to have been pretty clearly proven that they are not always made of nerve fibers. By far the most interesting form, however, is the plexiform neuroma, in which several hundred tumors are found on the various nerve cords. In one celebrated case, over 1100 distinct tumors were found on the nerves of the body. These cases are usually of congenital origin. Traumatic neuromata may follow a wound or partial division of a nerve. Of course more or less of a bulbous enlargement must be looked for normally on the central end of every divided nerve and will usually cause no trouble. Sometimes, however, the growth becomes too large, becoming excessively tender, and causing the most intense neuralgic pain.

Treatment.—Unless causing inconvenience by the pain it causes or by its bulk, a neuroma should be let alone. Excision is the only available treatment when it becomes necessary to do something to relieve the patient. Complete relief usually follows the excision, but amputation of neuromata often recur. In excising, if possible, remove the tumor from the nerve without cutting across it. This can generally be done. If not, then try and save a few fasciculi, which will preserve the continuity of the nerve and hasten the restoration of its functions. Where complete division is necessary, try and suture the divided ends, but even when this can not be done, restoration of function sometimes occurs.

TETANUS.

Tetanus is an infectious disease marked by tonic spasms of the voluntary muscles with distinct exacerbations. These contractions may be confined to the muscles of the lower jaw (trismus), or to certain other groups of muscles, or they may involve the muscles of the whole body. Tetanus may occur at any age. It is often epidemic among children, when it is known as trismus neonatorum. Males suffer oftener than females by about four to one. This disease is caused by a specific bacillus—the tetanus bacillus, first discovered by Nicolaier, and first obtained in pure culture by Kitasato. This bacillus is motile, grows at ordinary temperatures, forms a slender rod with rounded ends and may grow into long threads. The requirements of Koch's postulates are fulfilled by this bacillus, which is present everywhere, in surface soil and dust. This fact explains why it is that wounds which have been infected by dust or earth are so often followed by tetanus.

Morbid anatomy.—The anatomic changes in tetanus are slight indeed, when one considers the severe symptoms. There are no characteristic pathologic changes found in the brain, cord or neighboring peripheral nerves, only an extensive proliferation of cells being observed on microscopic examination.

Symptoms.—About the first to be noticed are a slight stiffness of the neck, tightness about the jaws and difficulty in mastication. At times a chilly feeling or actual rigors have preceded these symptoms. Tonic spasms of these parts now occur, the condition being popularly known as lockjaw. As the disease progresses, the features become fixed or convulsed from time to time, the angles of the mouth are drawn up, causing a sardonic grin—*risus sardonius*. As the disease advances spasms of the voluntary muscles occur, which cause very severe pain. The muscles of the back are usually attacked next in order of frequency after the muscles of the face. The body is bent backward so as to form a complete arch—the patient resting on the heels and head, a condition known as *opisthotonos*. The rectus abdominalis muscle has been torn in the spasm. Sometimes the condition known as *arthotonos*, in which the entire body is perfectly rigid, may occur. Less often the body is drawn forward—*emprosthotonos*—and still more rarely to one side—*pleurosthotonos*. The slightest irritation is enough to bring on a spasm, in which the most distressing pain is felt. Profuse sweating usually occurs during a paroxysm. The temperature in some cases is normal throughout; in others there is a marked pyrexia from the onset, the temperature reaching 105 or 106 degrees before death, and being 109 or 110 degrees, and even higher, soon after death. When death occurs it is usually due to exhaustion from the fre-

quent tetanic spasms, but sometimes death occurs during the paroxysm due to heart failure or asphyxia.

Diagnosis.—In well-developed cases it is easy. From strychnin poisoning it may be told by the fact that there is no rigidity, and that the jaw muscles are never involved early, if at all. In hydrophobia there is no stiffness of the jaws, and in the paroxysms the muscles of the neck and back are not affected.

Prognosis.—In all cases the prognosis is grave. The mortality in the past has been about 75 per cent. According to Hippocrates if patients live past the fourth day they usually recover. Favorable indications are: absence of fever, late onset of the attack and localization of the spasms to the muscles of the face and neck. From recent results it would seem that the death-rate in cases of tetanus in the future will be very much lowered by use of the tetanus antitoxin.

Treatment.—The treatment is both local and constitutional. The local treatment aims to bring the wound into as healthy a condition as possible. This must be done by thorough cleansing and swift antiseptic measures. The local treatment is of the highest importance, from the fact that the toxic agents are produced by the bacilli at the seat of injury. Tillmans recommends the use of the 1 per cent. solution of nitrate of silver, which destroys the bacilli and the spores very rapidly and certainly in one minute. It is doubtful if any good is obtained by nerve-stretching. I now wish to speak of the constitutional treatment. This consists of general measures and a specific one. We must try and remove all irritation and support the patient's strength by plenty of nourishment, as tetanus is a disease causing profound shock and debility. Have bowels and kidney active. Keep patient in a dark room with one attendant. Feed patient by catheter passed through the nose when necessary. Nutritive rectal injections may be used. Spasms are greatly relieved by chloroform given at repeated intervals, but it is more satisfactory to keep the patient thoroughly under the influence of morphin given hypodermically. Spinal irritation is greatly relieved by ice along the whole length of the spine. The ice can usually be left on for six or eight hours, but as it is such a powerful depressing agent, the condition of the patient must be closely watched. Many drugs have been lauded for use in this disease. From a physiologic standpoint, calabar bean is the drug that deserves the most attention, as it is antagonistic to the tetanic spasms caused by strychnin. It has, however, proven not to be a specific for tetanus. Extract *physostigmatis*, $\frac{1}{4}$ gr. should be given every hour until complete contraction of the pupil occurs, and this must be followed by stimulants to counteract the resulting depression. The London *Lancet* recently reports a case caused by the use of this drug.

Specific treatment.—This consists in the use of the antitetanic serum. I firmly believe, from results I have seen and from recent reports published, that any physician failing to use this remedy in a case of tetanus is guilty of criminal negligence. As a rule about 15 c.c. given twice a day, if necessary, will suffice. Every case will be a law unto itself. I believe, further, that we should use this serum as a prophylactic measure in cases where we have reason, from the nature of the wound, to fear that tetanus will follow. Having always found them reliable, I very much prefer the serums produced by Parke, Davis & Co. The conclusions I arrive at are:

1. Sciatica, often called a neuralgia, is generally a neuritis or a perineuritis.
2. The pain in neuritis is due to the pressure on the nervi nervorum, and therefore nerve-stretching is very beneficial.
3. Neuralgia, while it may occur in any part of the body, most commonly affects the fifth cranial nerve.
4. Neuralgia in very many cases is associated with anemia.
5. We should use electric treatment in cases of traumatic paralysis.
6. Antitetanic serum should be used as a protective agent in doubtful cases.
7. The mortality in tetanus will be very much lowered in the future.

ECHINOCOCCUS OF THE LUNGS.

Presented to the Section on Surgery and Anatomy at the Forty-ninth Annual Meeting of the American Medical Association, held at Denver, Colo., June 7-10, 1898.

BY CARL BECK, M.D.

NEW YORK CITY.

As is generally known, echinococcus disease is produced by the *tænia echinococcus*, a parasite whose domicile is in the intestines of the dog, sometimes perhaps also of the cat. Its length is four millimeters. It has four joints, the posterior of which is larger than the remaining three together. The implantation of this parasite causes the formation of hydatids, which grow into cysts and secondary proliferative cysts in various organs of the human body, particularly the liver.

The knowledge of the echinococcus disease dates as far back as to the time of Hippocrates, who described a "*jecur aquâ repletum*" which would open into the abdominal cavity. The same author speaks of an operation on an echinococcus cyst, before which operation adhesions between abdominal wall and cyst should always be produced by the use of artificial moxæ. The true parasitic origin of the disease, however, was not demonstrated until Göze, in 1782, recognized the characteristic heads and hooklets of the *tænia*.

The echinococcus disease is found in all parts of the world; yet with the exception of Iceland, some parts of Australia (Victoria and Tasmania) and the vicinity of Irkutsk, Russia, where it is endemic, it is but rarely observed. Especially rare is the echinococcus disease in this country, which explains fully why the American literature on this most interesting subject is so very scant.¹

The predilection of the echinococcus for the liver is quite natural. The vena portæ leads it by the shortest and broadest route, just as it carries the pyogenic embolus from an infected focus. The echinococcus is found much less frequently in other organs, for instance in the medulla of bones, the pleuræ, the spleen, the intestine, the heart, and still more rarely in the lungs. The literature of echinococcus of the lung is so meager that the following report may deserve record:

An Austrian, 38 years of age, 7 years in the United States, with the following family history: His father died when 61 years of age, from pneumonia; his mother of a brain lesion at

71; a sister died of tuberculosis of the lungs; five brothers are alive and well. The patient never had much association or contact with dogs or cats. About six years ago he had an attack of pleurisy with effusion. He was at first treated medically, and later the serous fluid was aspirated. After a slight improvement, lasting about nine months, he was taken sick again. This time he coughed violently, the expectorations containing much blood. He was treated then for consumption, and was refused admittance at several hospitals, on the ground of the diagnosis. At last he was admitted to a home for consumptives.

About two years ago a slight swelling under the right angle of the scapula appeared, and in the course of about four weeks it became slightly painful; sero-pus was revealed on incision, and some improvement followed, but the cough, accompanied sometimes by vomiting, persisted as before. At last the expectoration became fetid, and the house physician, while examining the sputa for tubercle bacilli, detected hooklets and fragments of cyst wall; the diagnosis of gangrene of the right lung, caused by the invasion of the echinococcus, was made, and the patient was sent to St. Mark's Hospital for operation. It may be added that jaundice was never present.

Nov. 22, 1897, when I saw the patient for the first time, I found the following conditions: A tall, emaciated man; a flat thorax, which expands symmetrically; the left lung is normal, but on the right side, anteriorly and below, there are tympanic sounds, and also râles during inspiration; posteriorly and below there is slight dullness; correspondingly, bronchial breathing and râles are found; the heart is normal; pulse 106, temperature 100.5 F.; the urine contains indican. The patient suffers intensely under vehement coughing spells, especially in the morning, which are always followed by expectorations of a most offensive odor. Sometimes there is dyspnea and also hemoptysis. The sputa amounts to about 200 c.c. in twenty-four hours, and contains pus corpuscles in abundance. There are fibers of the characteristic alveolar type, pigment, hematoidin crystals, disintegrated blood corpuscles, phosphate crystals, streptococci and leptothrix. Neither the bacterium coli commune, which was particularly looked for, nor the tubercle bacillus, could be discovered, nor were any hooklets or cystic fragments found. When the patient expectorates little, the dullness posteriorly is more pronounced, and the respiratory sounds are less audible than in the morning after copious expectoration. Then the bronchial respiratory sounds become more pronounced, again above the region of the fifth, sixth and seventh ribs, where sometimes amphoric breathing can also be perceived. Diagnosis: Lung cavity, caused by gangrene, induced by the invasion of *tænia echinococcus*.

November 24, after the usual aseptic precautions, pneumotomy was performed. In view of the weak pulse of the patient digitalin had been administered during the last forty-eight hours, and a saline infusion twice during the last twenty-four hours. Chloroform was given carefully. An incision reaching from the middle axillary line to the transverse process of the sixth dorsal vertebra was made, directly down to the bone, and by keeping the edges of this wound far apart it was possible to expose the fifth and seventh ribs, which now, together with the sixth, were resected. After a portion of the soft tissues also, with the costal pleura, was removed, the lung collapsed slightly, but soon assumed its former expansion. The edges of the cavity being well protected with sterile gauze, a strong aspiratory needle was pushed forward into the center of the exposed area, which yielded blood only. After various efforts in different directions were made in vain, the stylet tip of a Paquelin's cautery (such as I have advised in former publications on the technique of the operation for abscess of the lung, (Forty-eighth Annual Meeting of the AMERICAN MEDICAL ASSOCIATION), was introduced carefully into the center of the exposed area. After a little over an inch of the lung tissue had been perforated, a stream of rust-colored pus of a most offensive odor escaped with a loud noise, and at the same time the patient collapsed rapidly. A sponge was quickly forced into the opening, and under artificial respiration and energetic stimulation the patient rallied. On the following day the cavity was carefully washed, and much pus and detritus discharged, and it was drained by a large rubber drainage-tube, surrounded by iodoform gauze. The secretion was copious during the next four weeks, but its repeated microscopic examination revealed nothing extraordinary.

During the first week after the operation the temperature varied between 99 and 101 F., while the pulse was 90 to 100. The patient slept but little, and was tortured by coughing spells which were nearly as violent as formerly. The respiration on an average was from 30 to 36. As it seemed that there was some retention, probably due to the irregularity of the draining canal, I introduced my finger into the cavity, dilating

¹ Besides this case I had a chance but once to operate upon another echinococcus. It concerned a man aged 34 years, a German by birth, who had resided in this country for eight years and who also denied any particular correlation to dogs. The patient had shown an enlargement above the anterior surface of the liver. No jaundice. Several times a light serous fluid was aspirated, which, although a faulty procedure, was always followed by a slight improvement. May 26, 1892, he submitted to laparotomy at St. Mark's Hospital. Recovery was speedy and perfect.

it thoroughly: a large quantity of bloody pus was discharged again, and by a violent cough a thick membrane, rolled together like a cigarette, was expelled, which proved to be a piece of a cyst-wall. The patient now improved steadily, the discharge lost its odor and became very much less in quantity, and the temperature, pulse and respiration became normal. On February 6 the tube was discarded, and on February 21 the wound was found healed. All the patient complained of now was a sharp pain, which extended into the epigastrium when he tried to inspire deeply. Pressure above the large curvature caused considerable pain, so that when hyperacidity and nausea was noticed, a stomach ulcer was thought of, although no hematemesis was present. The treatment of these symptoms showed no result. The more the retraction of the large scar proceeded, the less intense these pains became, and so it was evident at last that the pain was caused by the process of scar formation in the lung tissue, during which the diaphragm, which undoubtedly had become adherent in the course of the disease, was drawn upward in this vicinity. Under the use of respiratory gymnastics and electricity these attacks disappeared slowly, and the patient was discharged cured June 20, 1898.

Whether the original implantation of the parasite in this case took place in the lungs (primary echinococcus of the lung), or indirectly from the pleura or liver by slow perforation, is not fully evident from the previous history. While the localization of the abscess, which had been incised two years ago, might slightly be looked at in favor of an origination in the liver, the symptoms of an affection of the lungs were predominant from the early beginning of the disease. That well-pronounced symptoms were absent for a long period, could be explained by the slow growth.

A resumé of the diagnostic points may be condensed as follows: 1. Whenever the symptoms of a chronic affection of the lungs become apparent, and pneumonia, circumscribed effusions, pyothorax and infectious diseases (particularly tuberculosis) can be excluded, the possible presence of echinococcus should be thought of, especially so when at a later stage there is violent cough and expectoration of blood and pus of a most offensive odor. 2. In those rare cases where the examination of the sputa fails to show the characteristic elements of the parasite, it should be considered that at the early stage of primary echinococcus the lines of dullness are irregular according to the shape of the cysts, and sharply pronounced, while later on, when it comes to the formation of an abscess cavity, they are replaced by tympanitic sounds. Accordingly there is also no abnormal temperature at the beginning, while later on the characteristic irregular temperature-curve points to pus retention. 3. Sometimes there is an expansion of the thoracic wall and a dilatation of its veins. If the abscess wall approaches the chest wall, bulging of the intercostal spaces becomes noticeable.

From this case we learn that the diagnosis of echinococcus of the lung is usually difficult. Its rarity prevents its general and thorough study, but it can fairly be assumed, on the other hand, that it is more frequent than is supposed, because on account of its difficult recognition it is often taken for a different disease. With our better means of investigation and our greater zeal, this disease will in the future be more frequently detected, and pneumotomy, the only proper therapy, will be more often resorted to.

RECENT EXPERIENCES IN MILITARY SURGERY AFTER THE BATTLE OF SANTIAGO.

BY N. SENN, LIEUT. COL. U. S. V.

CHIEF OF THE OPERATING STAFF WITH THE ARMY IN THE FIELD.

(Concluded from page 1171).

Case 18.—Scanlon, Company K, Third Cavalry, was wounded

on the second day of the battle of Santiago. The ball entered the chest through the third rib midclavicular line on the right side, passed downward and backward and escaped in the gluteal region on the same side, after perforating the ilium (Fig. 21). The ball must have passed through the lung, diaphragm and liver. Hemoptysis slight, but distressing nausea, vomiting and pain. Admitted to the hospital ship *Relief* July 15. At that time he had a constant temperature ranging between 100 and 102 degrees F., vomiting, diarrhea and rapid emaciation. Great pain over the liver and ascending colon. Hemothorax and marked swelling in the region of the liver and abdominal cavity on the right side. Examination of urine negative. Owing to the great debility and pronounced anemia it was not deemed advisable to resort to laparotomy.

Case 19.—Harry Mitchell, Company C, Seventh Infantry, was wounded July 1. The bullet entered over the right acromion process, passed through the apices of both lungs and escaped through the second intercostal space above the right nipple (Fig. 22). No hemoptysis at any time, dry cough and a moderate hemothorax on the right side. Has suffered from

Fig. 21a.

quotidian form of malarial fever, which is yielding to quinin. A speedy and complete recovery is expected.

Case 20.—Lieut. John Robertson, Company G, Sixth Infantry, received a gunshot wound of the upper third of right thigh about 10 o'clock July 1. The profuse hemorrhage was partly controlled by an improvised tourniquet applied by an officer of the line. He was carried to the rear by the men of his company, and while thus conveyed he was shot in the left breast, the bullet entering just below the left nipple and passing through the chest in an antero-posterior direction (Fig. 23). He was wounded a third time, the bullet grazing the inner side of the left knee. The first dressing was applied in the First Division Hospital. The fracture of the thigh was dressed by the use of a long splint. From here he was sent, on July 9, to the Third Division Hospital, and two days later was brought on board the *Relief*. At this time both chest wounds were healed. The thigh wounds remained aseptic. A radiograph showed great displacement of the fragments by overlapping. The fracture was then treated by confining the limb upon a

double-inclined plane, consisting of a hollow posterior splint made of the sheath of the leaf of the cocoa palm, to which was added an anterior thigh splint of wire gauze. After dressing, the limb was placed in a sling. No pulmonary or pleuritic complications.

Case 21.—Henry T. Darby, Company D, Thirteenth Infantry, received a perforating gunshot wound of the chest July 1. The ball entered on the right side, above the angle and at the outer border of the right scapula, passed through the chest and escaped through the fourth intercostal space in front, on the opposite side, two inches outside of the mammary line (Fig. 24.) When the patient came on board the *Relief*, July 9, he complained of great difficulty in breathing; he was pale and greatly prostrated; temperature 102 degrees F. The physical signs indicated the presence of a copious pleuritic effusion on the left side. The chest was opened by an incision through the sixth intercostal space, in the axillary line, July 11. About three pints of fluid blood escaped. Gauze drainage. The lung expanded rapidly and the patient commenced to improve.

Fig. 21b.

No further doubt can remain in regard to the difference in the mortality of gunshot wounds inflicted with the large and small caliber bullets. The cases related above appear to prove that the danger incident to gunshot wounds of the chest made by the small projectile, consists in complicating injuries involving the heart and large blood-vessels, and that in the absence of such injuries the prognosis is favorable. It seems that empyema is a rare remote result of such injuries. Rib resection and free incision and drainage of the chest in such instances must be reserved for cases in which a positive diagnosis of empyema can be made. The safest and best treatment for hemothorax requiring operative interference is tapping and evacuation by siphonage.

GUNSHOT WOUNDS OF THE ABDOMEN.

Our recent experience in Cuba has more than ever confirmed my conviction that not infrequently cases of penetrating gunshot wounds of the abdomen will recover without active surgical interference. For years I have maintained, as the result of clinical experience and experiments on the cadaver, that a bullet may pass through the abdomen on a level and

above the umbilicus in an antero-posterior direction without producing visceral injuries demanding operative intervention. Elsewhere the results of my experience and experimentation concerning such injuries have been published. If the bullet traverses the small intestine area it is more than probable that from one to fourteen perforations will be found.

Fig. 22.

Fig. 23.

Four laparotomies for perforating gunshot wounds of the abdomen were performed in the First Division Hospital, the only ones, to my knowledge, during the Cuban Campaign.

All of the patients died. This unfavorable experience should not deter surgeons from performing the operation in the future in cases in which from the course of the bullet it is reasonable to assume that the bullet has made visceral injuries which would be sure to destroy life without surgical interference. In other cases the employment of diagnostic tests for the purpose of demonstrating the existence or absence of intestinal perforations will enable the surgeon to decide what course to pursue. Abdominal section is always justifiable in cases of internal hemorrhage sufficient in amount to threaten life.

Fig. 24a.

A number of cases of gunshot wounds of the abdomen have been related in connection with gunshot injuries of the neck and chest, in which the cavity of the chest and abdomen and their contents were implicated at the same time, and which are on the way to recovery without laparotomy having been performed. I have seen a number of cases of perforating wounds of the abdomen in the First and Third Division Hospitals that were on a fair way to recovery without operation before they were sent home on transport ships. In most of these instances the bullet wounds were either in the umbilical

Fig. 24b.

region or one of the iliac fossae. The following case presents features of more than usual clinical and surgical interest:

Case 22.—J. F. Taylor, Company D, Tenth Cavalry, was wounded July 2. At the time the injury was received he was in the ventral prone position. The bullet entered the left shoulder in the infra-spinatus fossa one inch below the spinous process of the scapula, and passed downward and inward and lodged under the skin in the median line, two inches above the umbilicus (Fig. 25). Hemoptysis considerable during the first

day, when it gradually subsided. He complained of great pain and tenderness in the right side of the abdomen. No vomiting or symptoms of more than a circumscribed peritonitis. An abscess formed in the abdominal wall, which was opened July 20, and the bullet was removed. From this time on the patient improved rapidly.

GUNSHOT WOUNDS OF THE EXTREMITIES.

It is a source of gratification to know that very few primary amputations were made for gunshot injury of the extremities. All of the surgeons realized the importance of conservative measures in the treatment of such injuries, and limited amputation to cases in which the condition of the soft tissues precluded such a course. A number of secondary amputations became necessary to save life in cases of infected compound fractures, usually complicated with injury and infection of the adjacent joint. Two cases of traumatic aneurysm are now on

Fig. 25a.

board the *Relief*, one an aneurysmal varix, the other an aneurysm of the femoral artery.

Case 23.—Captain Mosher, Company G, Twenty-second Infantry, received a bullet wound July 1, during the advance on Santiago. Those who saw the patient first assert that the hemorrhage was severe, and that the patient lost consciousness. He was removed to the First Division Hospital and transferred July 10 to the Third Division Hospital, and the following day he was brought on board the *Relief*. I examined the patient at the front five days after the injury and confirmed the diagnosis made by the attending surgeons, who had recognized the anatomic nature of the aneurysm.

The wounds healed by primary intention in less than two weeks. One wound is in the middle of Scarpa's triangle and the other at the level of, and one inch posterior to the great trochanter on the same side. From the fact that there is, as shown by the radiograph, a piece of the jacket of a bullet in

the right popliteal space, it is probable that he was wounded by a plunging fire and that the bullet inflicted the latter wound after emerging from the wound in Scarpa's triangle. The wound in the popliteal space is suppurating. Patient is very anemic and weak. In the triangle directly under the wound there is a pulsating swelling in the direction of the femoral vein, which extends to Poupart's ligament. Fremitus and the characteristic bruit extend a considerable distance above and below the communicating opening between the artery and vein. The treatment consists in rest and tonics. General health of the patient is improving, but there is no change in the local condition. The mental condition much impaired since the injury is gradually improving.

Case 24.—John J. Welch, Company M, Second Massachusetts Volunteers, was wounded July 1. The bullet entered the middle and back of Scarpa's triangle, three inches below Poupart's ligament, directly over the femoral artery, and escaped at a point corresponding with the gluteal crease and to the outside of the femur on the same side (Figure 26). Not much hemorrhage. A well-marked aneurysm developed,

Fig. 25b.

Fig. 26a.

Fig. 26b.

presenting all the physical signs characteristic of such a pathologic condition. The swelling is somewhat elongated, a little larger than a hen's egg, and has not increased in size since the patient came on board the hospital ship. The leg is somewhat edematous and painful. A number of gunshot fractures of the thigh and leg have become infected and are now being treated by establishing free tubular drainage and resorting to frequent or continuous antiseptic irrigation. Owing to the want of reliable plaster of Paris, we had to resort to various kinds of splints, single and double inclined plane, in effecting immobilization. The sheath of the leaf of the cocoa palm has served as an excellent material for this purpose. There is every prospect that most of these cases will ultimately recover with useful limbs.

In conclusion I desire to thank Acting Assistant-Surgeons Metcalfe, Torney, Greenleaf, Hartsock, Morrow and Schultze for valuable assistance in preparing this communication.

SOCIETY PROCEEDINGS.

Chicago Academy of Medicine.

Regular Meeting, Oct. 14, 1898.

Dr. GEORGE F. BUTLER occupied the chair.

Dr. G. F. HAWLEY of Chicago presented a paper entitled

CHRONIC POST NASAL CATARRH.

He said that the title is applied to a low grade of chronic inflammation located in the post-nasal space. The condition is found at all periods of life, from the nursing infant to the nonagenarian. It is so prevalent in America that it has been entitled by Mackenzie and others "American Catarrh." Whether this prevalence is due to climatic influences or to predisposing factors in those living on this side of the Atlantic, is a mooted question. That post-nasal catarrh may be associated with a neurotic diathesis, due to degeneracy, and also to intra-utero-vaginal states, can hardly be questioned. The functions of life are more or less easily disturbed in such cases, resulting in a predisposition to all types of disease, especially those affecting the glandular system. It is particularly noticeable in the torpid and erethistic types of the tuberculous diathesis, characterized by very light or very dark hair, light or dark eyes, a dark, pallid or light complexion, much perspiration, small blood-vessels, slow, feeble or rapid pulse, and want or excess of energy in mental and physical functions. Nowhere is there a richer supply of glands than in the post-nasal space, hence this is naturally affected early by the condition mentioned. In nearly 90 per cent. of all chronic catarrh the post-nasal space is affected. It has been claimed that a perfectly healthy post-nasal space can hardly be found in this country. The far-reaching baneful effects of this disease can not be questioned, since many secondary disorders affecting the upper air-passages and bronchi are due to post-nasal catarrh. It is the *bête noir* of the singer and public speaker. It is the frequent cause of suppurative and catarrhal inflammation of the middle ear both in the young and old. It is a strong factor in producing deafness in after life. This constant state of inflammation disturbs the circulation, and by causing congestion and hypertrophy of the turbinates, prevents free drainage and obstructs to a greater or less degree the passage of air through the nose.

The causes of this disorder are divisible into predisposing and exciting. Judging from the extensive and early manifestations of this disease, the predisposing causes are inherited or congenital, from maternal leucorrhœa, etc. The exciting causes are sudden changes of temperature, and diseases affecting the upper air passages, such as measles, scarlet-fever, diphtheria, etc. The symptoms are so well known that it is hardly worth while to repeat them here.

The clinical aspect of the disease varies according to the age of the patient and the duration of the trouble. In the early stage, particularly in the young, the post nasal space is frequently found more or less filled with masses of tissue, giving to the touch a sensation similar to that of angleworms (adenoid growths of Meyer). This mass is easily broken down and exceedingly vascular. Later on, instead of masses of tissue, isolated growths or nodules occur, more or less evenly distributed over the vault, distinct and independent of each other. These, in the early stage of the disease, are also exceedingly friable. Later these growths become fibrous in character and are difficult to remove. This form of the disease is usually associated with granular pharyngitis. Often, as in cases of old chronic suppurative inflammation of the middle ear, the mucous membrane appears swollen and soggy, seemingly soaked with mucus or serum. Again the mucous membrane, though generally healthy in appearance, presents, in the median line, folds of hypertrophy tissues. These are parallel to each other and run upward from behind the soft palate to the vault. In all these conditions the mucous membrane is highly congested, causing that sense of fullness so distressing to the sufferers from this disorder. He has also found at the median line and near the vault, single cystic growths or swellings about the size of a split bean, smooth to the touch and with the sides gradually running into the adjacent mucous membrane. This is easily destroyed by the finger, exposing a pocket-like depression with smooth and hard walls. Occasionally the mucous membrane is covered by highly vascular granulations, which, though hardly visible on examination, give to the finger a sensation as if passing over velvet or plush. All these abnormal conditions not only prevent a cure, but cause the many distressing symptoms associated with this form of the disease. The importance, therefore, of a thorough examination and treatment of the post-nasal space in all catarrhal affections of the upper air-passages can not be too

strongly urged upon the profession. In no other way can the practitioner expect to accomplish any permanent good, as here lies a strong factor of causation.

The prognosis is good if seen in time and treated properly. If not, the condition gradually grows worse, affecting the neighboring parts and producing ear complications and finally inflammation of the pharynx, larynx and bronchial tubes. Due to disturbance of circulation, the nose becomes gradually closed by thickened mucous membrane, until its natural function is almost entirely destroyed, causing mouth-breathing with all its ill effects.

The treatment is constitutional, surgical and medicinally local. Constitutional treatment depends upon the condition of the individual. It should tend to the building up and supporting of the general health. But few cases of post nasal catarrh can be cured or even relieved without surgical interference, the removal of all outgrowths and diseased tissues. Local applications, in whatever way applied, are for thoroughly cleansing and stimulating the parts affected. Up to the present time attempts to cleanse and medicate the post-nasal space have proven unsatisfactory. The anatomic relations of the parts are such that to thoroughly cleanse and medicate the diseased tissues by any instrument in use is practically impossible. It is due to this fact, more than to the obstinacy of the disease, that a larger percentage of cures does not result. The spray is the best means to accomplish this end. As generally used by the profession, it is open to serious objections. While the atomizers furnished by the instrument makers may thoroughly cleanse the anterior chamber of the nose and the pharyngeal walls, they can force but little medicament into the post-nasal space in the form of spray. The spray soon becomes

new instrument may be good or it may be bad, but in any event he overlooks the etiology and pathology of the condition. He presumes that some medicament sprayed into the nasopharyngeal space by means of his device, will cure a large percentage of cases so treated. We regard the so-called post-nasal catarrh as a symptom of one or more conditions, which are usually found in the nose. A few instances illustrating the point are: 1. Polypoid degeneration located in the posterior part of the nasal chamber would, by occluding the nares and giving rise to an acrid discharge into the post nares, excite an inflammatory action of a low grade in the mucosa of the post-nasal space. 2. An inflammation of the posterior ethmoidal or sphenoidal cells would give rise to a discharge into the post-nares, thereby giving rise to catarrhal inflammation of the membranes of the parts. 3. Dry rhinitis, rhinitis with collapse, and atrophic rhinitis, diminish or abolish the supply of moisture which is physiologically supplied to the inspired air. The nasopharynx and pharynx attempt to supply the deficiency. Overstimulation results, and we have chronic post-nasal catarrh as a result. 4. Post-nasal adenoids are attended by the same conditions. So one might continue to name conditions which give rise to so called post-nasal catarrh. The point I wish to make clear is that post nasal catarrh must be first thought of as a result of one or more antecedent conditions. After having recognized it as such, we must determine which of them are present in the case under consideration. Having determined the cause or causes we are ready to think of the treatment. If the catarrh is caused by nasal polypi, we may hope for relief by removal of the same. If caused by catarrhal or suppurative inflammation of the ethmoidal or sphenoidal cells, we must cure these conditions before hoping

a stream which flows along the inferior meatus until it falls either into the pharynx or, by the aid of the soft palate, passes out into the adjacent nostril. On account of the extreme sensitiveness of the mucous membrane lining the nasal passages, the practitioner is, moreover, restricted in selection of medication and in its strength. Silver nitrate, for example, one of the best remedies in treating post-nasal catarrh, can be used, if at all, only in very weak solution, on account of the strong reaction produced in the nose. The nose, whether healthy or diseased, must receive the full effects of all medicament intended for the post nasal space alone. If the attempt be made to spray back of the soft palate, the time allowed for the treatment is so short, from gagging of the patient, that but little effect can be produced upon the diseased tissues. The same objection exists to the use of powders. The brush is not only disagreeable to most patients, but gives unsatisfactory results as well.

One object of this paper is to bring to notice an improved instrument which overcomes many of these difficulties. It is so constructed that it can be inserted through any nostril, no matter how small, until it reaches the post nasal space, where a medicament, by means of a spray, can be applied directly and forcibly against the entire diseased surface. The strength of the medicament is graduated by the amount of spray used, which again is gauged by means of a small set screw at the head of the bottle containing the medicament.

Dr. WILLIAM L. BALLENGER—Dr. Hawley's thesis treats of a condition, the relief of which often baffles the efforts of the rhinologist. The very stubbornness of the condition tempts him to devise some new method or instrument for treating it. His

to relieve the post-nasal catarrh. If hypertrophy of the posterior ends of the inferior turbinated bodies exists, we remove them before addressing particular attention to the post nasal space. And so we can not say any particular method or instrument will cure chronic post-nasal catarrh. When Dr. Hawley says that hypertrophies of the nose disappear after his spray-treatments of the post nasal space, he certainly is in error. Hypertrophies do not disappear so easily. If an hypertrophy exist, it will only disappear by surgical interference. When Dr. Hawley accuses post-nasal catarrh of causing most nasal disorders, I think he has the cart before the horse. It is a well-recognized pathologic fact that the post-nasal disorder is usually a secondary, and not a primary, affection. I must, therefore, disagree with almost every proposition set forth in Dr. Hawley's thesis. I recognize that chronic post-nasal catarrh is somewhat relieved by post-nasal washing, but I do not believe any considerable number of cures result from such treatment.

Dr. RIES wished to ask Dr. Hawley as to the influence of the maternal parturient canal in producing adenoids in the child as he had understood from the Doctor's paper that the gonococcus of the maternal canal exercised an influence in producing chronic conditions of the mucous membrane of the child leading up to adenoids.

Dr. KIERNAN said that in adenoids two factors had to be taken into consideration—the constitutional condition and the local exciting factor. Adenoids very frequently occurred in degenerates and, all other things being equal, the gonococcus was most likely to be present in the vaginas of degenerate women, or of women who had degenerate husbands. The lat-

est researches on the subject with which Dr. Kiernan was acquainted were those of Dr. O'Toole of San Francisco, which had been reported in the last volume of the JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION. The gonococcus was an exceedingly obstinate infector of mucous membranes, and the effects of its presence were certainly conducive to secondary mixed infection by the streptococci and staphylococci. Hence it could be seen that children born of mothers infected by gonococci might not only have contagious ophthalmia, but also nasal and buccal disorders.

Dr. HAWLEY, closing the discussion—Dr. Ballenger is in error when he states that I claimed in my paper that medicaments sprayed into the naso-pharyngeal space by means of my device will cure a large percentage of cases so treated. I did say, however, that but few cases of post-nasal catarrh can be cured or even relieved without surgical interference; also that the anatomic relations of the parts are such that to thoroughly cleanse and medicate the diseased tissues by any instruments in use is practically impossible, and it was due to this fact that a larger percentage of cures did not result. The spray, or some local application, as I expressly stated, constitutes adjuvant treatment. Surgery alone, while it may remove the cause, rarely cures the secondary disease of the mucous membrane. So far as my device is concerned, I simply claim that it offers a superior method of applying such medicaments as may be deemed advisable by the surgeon.

The term post-nasal catarrh, as now used, does not imply a symptom alone, but a disease, a low form of inflammation of the mucous membrane with its many glands and follicles, and presenting various clinical and pathologic conditions, some of which I have herein noted. Whether some or any of these conditions depend upon preexisting trouble in the nose, I neither affirm nor deny. That nasal trouble is often due to preexisting disease in the post-nasal space, I think can at least be conceded. When we note the frequency of the disease, its early manifestations, its baneful effects upon the ear, the throat, and even the bronchial tubes, can we not feel assured that it is also a strong factor in producing trouble in the nose, especially when we see, as I have seen in children, all these conditions—not only in the ear, throat, etc., but in the nose itself—improve by treating the post-nasal space. I think the Doctor is mistaken in his statement that it is a well recognized pathologic fact that post nasal disorder is usually a disorder secondary to nasal affections, and not a primary one; that is, if he understands post nasal catarrh as I understand it, an actual inflammation existing in the post-nasal space, and not merely a running at the back of the nose due to polypoid or sphenoidal disturbances. Post nasal catarrh can and does exist independently of any nasal trouble, due to constitutional dyscrasia, especially noticeable in the tubercular and weakened type of the Xanthous variety of mankind. That post-nasal catarrh is frequently caused by a lithemic diathesis, as described by Musson, Robinson, Allen and others, I think cannot justly be questioned, and that it is found in the newly-born, through maternal leucorrhea, as described by O'Toole, must also be admitted. "Post nasal catarrh" is a bad term to use, admitting of too many views as to its meaning, but it is the best we have at present. It is due to this fact, I think, that Dr. Ballenger and myself differ so materially regarding the etiology, pathology and treatment of this disease.

Dr. CARL THEODOR GRAMM presented a paper on the subject of

IMPLANTATION OF FOREIGN OBJECTS IN THE MAXILLÆ.

He explained the paper to be a preliminary report of a study of bone degeneration. Its practical side dealt with the possibility of implanting in the processes of the maxillæ, and having firmly encapsuled there, substitutes for the roots of teeth that have been lost by decay, trauma, or pyorrhea alveolaris—substances other than ivory, or roots of living or desiccated teeth, all of which are prone to resorption. The author reviewed the character of the maxillæ and the phenomena of bone regeneration in them and pointed with emphasis to, citing a number of experiments and authorities in support of, the claim that the recuperative forces in this bone are markedly in advance of other bones of the body. He then went on to say: "whether in the presence of a mechanic irritant, a substitute for natural roots such as I will describe below, from this bony structure, rich in resources for repair and readily adaptable to altered conditions, would develop a sclerotic envelope for the substitute, or whether the process would be one of degeneration and sloughing is the question to be weighed. It is a question taking us at once into the field of bone resorption and regeneration, bone inflammation and its sequels." The author cited and criticised the experiments and conclusions of thirty-nine authorities who have studied the phenomena of bone develop-

ment. His own experiments, which were carried only through the preliminary stages, were performed upon six dogs, and consisted in removing an upper pre-molar in each of them, freely enlarging the socket and implanting an artificial root made of lead, which was held firmly in position by a mechanic device. The apical portions of these lead roots were bulbous, and at their middle were shallow grooves, which, when filled in with fibrous or osseous tissue, would favor their retention. Four of these dogs were killed in from three to six weeks after the operations, and sections of the jaws removed in order to demonstrate the development of new bone under various conditions. As the result of this work, he holds that further experiments, in which sufficient time is to be given for the solidification of new growth, will verify the hypothesis which formed the basis of this preliminary work, to-wit, that a mechanic irritant such as he proposed, will under favorable conditions cause a sclerotic envelope to be formed about it sufficiently firm to withstand the pressure from articulating teeth. He seeks an analogy in the chronic osteitis in which no rarefaction of bone occurs; in which new growth slowly ossifies, and the Haversian canals and cancellous spaces diminish—a condition commonly known as osseosclerosis. The article was illustrated by photo-micrographs and lantern slides from the author's laboratory.

Dr. EUGENE S. TALBOT—About twenty years ago, Dr. Younger first brought prominently before the profession the implantation of teeth; however, the better educated men of the profession looked upon this practice unfavorably. He claimed that a tooth which had been out of the mouth indefinitely could be cleaned by scraping off the peridental membrane and debris, and disinfected, and, after drilling a hole in the jaw-bone and being implanted, would produce a new peridental membrane, and apparently be as good a tooth as any. He went so far as to state that the tooth of a mummy which had been dead for thousands of years would be implanted into the jaw of a patient at the International Medical Congress, held at Berlin, and that it would grow firm and become useful indefinitely. This was done, but the operation was unsuccessful, the tooth only lasting a few days. Many teeth have been implanted, but a very small number have proven a success. I have never heard of or seen a case where a new membrane had been produced. These teeth have been treated by the system like any other foreign body, and expelled either bodily or by absorption. Therefore, I have never taken kindly to this operation. The essayist has undertaken some very valuable experiments, and I wish to congratulate him upon the work he is doing. Much may be learned from it. He has not, however, brought us any tangible consideration this evening. His work is only fragmentary, and no definite results have been presented. The work is so incomplete that it is hardly consistent to bring it before this body this evening. Such work requires much time and many experiments to give us definite results. I trust he will continue his work and, when complete, give us material of great value.

Dr. A. E. BALDWIN—This is a subject that has been of very great interest to me. I have not made any original investigations myself, and have consequently been more interested in these experiments than I otherwise would be. While congratulating the writer of the paper upon his experimental work, I can not help but agree with the previous speaker in concluding that the experiments are on a line which will not be productive of any great benefit. Ten years ago, in an interview with Dr. Younger, he claimed to me that these operations of implantation of teeth, which are directly in the line of this paper, would be recognized as a great success all over the country in a few years. I told him then, as I say now, that if the principles laid down by Dr. Younger, which are apparently the same as those of the writer of this paper, are true, we shall have to relearn our histology and physiology. Nature sometimes tolerates these foreign bodies simply in a mechanical way, but it seems to me as though we have not evidence of any natural union between the implanted bone or tooth and the alveolar process.

Dr. GRAMM, in closing the discussion—It is true that the work is incomplete and does not present final conclusions. I hesitated somewhat on that account to bring it before this body, but concluded finally, after having found abundant precedent to do so. I believe it is quite frequently the case that scientific bodies lend an ear to notes of experiments that are preliminary. The criticism which Dr. Talbot passes upon Dr. Younger does not apply to the work under consideration. The resorption of an osseous structure implanted is a probability recognized by histologists fifty years ago. The foreign material implanted in the jaws of these dogs is non-absorbent, hence the interest in this work does not center in the fate of the tooth-root implanted, but rather in the degree of toler-

ance exhibited by the osseous tissue of the alveolar process. It has not been proven that the alveolar process in particular, this structure of exceeding vitality, will not tolerate a foreign substance, and no measure of general statement, unless founded upon experiments made directly upon the maxillæ, can be accepted as criticism of undoubted value.

The Second Northern Congress of Internal Medicine.

Held at Christiania, Norway, in August.

This congress gathered a representative assemblage of Scandinavian physicians from the Northland countries, and even one from Scandinavian Chicago.

ORGAN-THERAPY.

REIERSEN reported encouraging results from the use of "testicle extract," especially in tabes, 12 cases rendering morphin unnecessary, but the general trend of opinion seemed to be unfavorable.

SCHJÖTTE of Copenhagen stated that he had been extremely successful with thyroid treatment in obesity, combining it with moderate under-feeding, but plenty of albumin. He declared the profession over-timid in regard to thyroid treatment, and too apt to transfer to obesity the disturbances caused by it in myxedema, which should not be compared with it at all.

FABER called attention to the cutaneous hyperesthesia of certain portions of the abdomen which sometimes accompany gastric troubles, (25 of his cases) but yield to faradization, etc. Others confirmed his experience and warned against the mistake of diagnosing a gastric ulcer from this undoubtedly hysterical symptom.

ARTERIOSCLEROSIS.

Professor EDGREN's address on this subject was based on a study of 124 cases. He found syphilis the most frequent antecedent (age, 40 to 46 years), next alcoholism (age 51 to 53), hereditary, malaria and lead poisoning. No special cause could be discovered in 12 cases, (average age 66) evidently the pure senile form.

Professor RYNEBERG treated the subject from the clinical and therapeutic point of view, classifying arteriosclerosis as: 1, the local or typical syphilitic form, affecting the arteries of the brain or the aorta; 2, granular-atrophy sclerosis of the smaller and medium vessels, with secondary hypertrophy of the heart; and 3, generalized sclerosis of the large and medium arteries—the senile type. He advised prophylactic measures to insure regularity in the functions—diuresis, gymnastics, etc., with potassium iodid continued for several years; tonics, and antisyphilitic treatment as indicated.

Prosector GADE described the anatomic alterations in this affection, which seem to be of a purely degenerative character, suggesting injury to the tissues of a chemist's nature.

Professor LAACHE disputed this toxic etiology and attributed the chief rôle to the arterial pressure, citing the rarity of the process in the pulmonary arteries.

MYGGE emphasized the "Importance of Radiography in the Diagnosis of Aneurysm of the Aorta."

RASCH stated that twenty-five aneurysms of the aorta were discovered in the course of 3165 necropsies at Copenhagen. Syphilis was certain in 56 per cent., and probably in 82 per cent. He calls the aneurysm-forming process a chronic fibrous aortitis.

STORM BULL reported two cases in which he had based his diagnosis on the pulsation in the larynx, confirmed by the necropsy.

HANSSEN described certain accidental heart sounds, observing that a whistling sound in pericarditis indicates synchia.

Professor MEDIN noted the increasing frequency of "Morbus Barlowi" in Stockholm, among children with syphilitic inheritance, rachitis, etc. He described fifteen observations, with four deaths. Three of his cases had no trace of rachitis. He found fresh lemon juice the most effective treatment.

HALLARGER commented on the comparative temperature in the rectum and axilla as an aid in the "Diagnosis of Hysteria." There is no difference between them, as in normal conditions, or it is reversed; sometimes the axillary temperature is the higher by two to three-tenths of a degree.

Professor GRAM endorsed peronin as a valuable acquisition, to take the place of morphin, using twice the dose. He has found it effective in sixty cases of neuralgia, nervous sleeplessness and tuberculous cough.

USTVEDT reported that Widal's sero-test failed in over 26 per cent. of the cases in a recent extensive epidemic of typhoid, while it had resulted positively in 100 per cent. during the previous epidemic.

Professor LAACHE closed the scientific communications with

an address on "Paroxysmic Tachycardia," which he considers a neurosis.

The Christiania physicians own a commodious building for their local gatherings, which was the envy of many visitors, and the excursions to the sanatoria, etc., in the neighborhood, aroused much enthusiasm for the beautiful scenery and general appointments. The Congress will meet at Copenhagen next year.

SELECTIONS.

The Rabietic Bacillus.—Foll, Rivolta and Spinelli claimed to have detected a bacillus the specific character of which was made highly probable by Sanfelice, who, employing a special staining process, demonstrated its presence in large numbers in the spinal cord of a boy who had died from hydrophobia. Memmo of Rome confirmed the observation of Sanfelice and proved the virulent character of the micro-organism, which he detected in several cases of rabies, but quite recently he has succeeded in cultivating it in artificial media, and in reproducing by inoculations with these cultures the disease with its distinctive characters, in dogs, rodents and birds respectively. These experiments and observations, which fulfilling the most stringent demands of bacteriologic criticism, leave no room for doubt, are described in the *Centralblatt für Bakteriologie*. He found the microbe in the cerebro-spinal fluid and the substance of the brain and spinal cord, in the saliva and parotid gland, and in the aqueous humor of four dogs dying from the natural disease, and of rabbits, guinea pigs and pigeons, in which it had been produced by inoculation. It grew better in fluid than in solid media, the best being bouillon with glucose slightly acidulated with tartaric acid. The growth did not become manifest under a week, and was easily arrested by "air infection," as through the access of dust from the laboratory. Inoculated with cultures of the fourth generation, purified by successive plate cultures, guinea-pigs and rabbits developed symptoms of paralysis of the hind limbs, etc., after from eleven to twenty days, and died from the paralytic form of the disease. With dogs the inoculation was prolonged to from thirty to sixty days, when they were attacked with all the symptoms of typical natural rabies. Though Memmo does not suggest the application of his discovery to the prophylaxis of hydrophobia it is not impossible that artificial cultures may be found capable of definite attenuation so as ultimately to simplify the methods adopted by Pasteur.—*London Lancet*, September 17.

Destruction of Locusts by Arsenic.—Physicians are so frequently consulted regarding crop pests, that we reproduce, in part, an account of the means found successful in Natal, South Africa, in combating the locust scourge. It is quoted from the *London Times*, Sept. 23, 1897: The mixture used is prepared by heating four gallons of water to boiling point and then adding one pound of caustic soda. As soon as this is dissolved, one pound of arsenic is added, after which the liquid is well stirred and boiled for a few minutes, care being taken that the fumes are not inhaled. Being poisonous, the mixture is kept under lock and key; but, when required for use, half a gallon of it is added to four gallons of hot or cold water, with ten pounds of brown sugar. A still better preparation is made by adding half a gallon of the poisonous liquid to five gallons of treacle. Maize stalks, grass, etc., dipped in the mixture, are placed along the roads and in the fields, and the material can also be splashed with a whitewash brush upon anything which the locusts are known to have a liking for. Attracted by the odor of the sugar or treacle over a distance of as much as 100 yards, the locusts will eat of the mixture and die. These are eaten by other locusts, and in a few days' time the ground may become strewn with the dead bodies of the insects. With ordinary care, no risk of poisoning any human being is incurred, while the small quantities of the material on a piece of grass or maize stalk is said to be insufficient to injure stock of any kind.

Fowls have been known to feed without injury on the arsenic-destroyed locust. The evidence adduced indicates that "hoppers," however numerous, can be destroyed in a few days, and the crops thus saved from their ravages. Should the winged locusts swoop down later in the season, the crops, in virtue of the vigor acquired from their early unchecked growth, will be in a far better condition to withstand attack. Arsenic is quite effective in destroying flying locust; but, as they come and go very suddenly, it is difficult to have the poison in readiness at the critical moment, and hence the most deadly blow can be dealt at the pest when it is in the hopper stage. One Natal cultivator cleared his farm, occupying 700 acres, of locusts in ten days by means of the arsenical mixture. As is well known, arsenic forms the basis of most of the sheep dips in common use, and it may be that the efficacy of arsenic as an insecticide in the fleece of the sheep will find a parallel in its application as a locust destroyer in the vast wheat fields of the Argentine and elsewhere.

PRACTICAL NOTES.

Radiography of Fetal Lungs.—Atelectasis is readily distinguished in a radiograph of a fetal lung, and can thus be demonstrated in court in doubtful cases.—*Gazz. d. Osp.*, September 4.

Potion for Whooping-Cough.—Koplik recommends the following in the dose of half a teaspoonful three times a day: Tincture of digitalis 1 gm.; antipyrin 2 gm.; elixir paregoric 4 gm.; syrup of tolu 60 gm.—*Semaine Méd.*, October 19.

Extraction of an Incarcerated Pessary.—With the Gigli saw, the accessible portion of the pessary is sawed off, and the pessary can then be revolved until the plane left by the excision is brought opposite the projection that opposes its exit, when it will easily slip out.—*Semaine Méd.*, October 19.

Carbolic Gangrene.—Ponzio claims that gangrene following the use of a phenicated solution is due to the compression of the bandage arresting the circulation. If a standard solution is used and non-compressing bandages ordered, neither the druggist nor the surgeon are responsible for the gangrene, which, if it occurs under these conditions, must be caused by some idiosyncrasy.—*Gazz. degli Osp.*, September 11.

Potassium Permanganate in Lupus.—Kaczanowski has cured thirty-four cases by dusting the surface with 2 to 5 milligrams of potassium permanganate, after removing the crusts with vaselin and warm soapy water. One application proves sufficient; the scab falls in fifteen days and the patch heals. A nitrate of silver salve hastens the cicatrization. The application of the permanganate is painful, but bearable, and no worse than other caustic remedies.—*Semaine Méd.*, October 19.

Non-toxicity of Orthoform.—Two cases are reported in the *Munich Med. Woch.* of October 18; one an extensive cancer of the mamma and the other decubitus sores (morphinomaniac), in which orthoform was used every day for months to relieve the pain, with complete success and without the slightest symptom of intoxication. In the first case 4266 gm. were used in five months, and in the second 5600 gm. since last March, or 15 gm. a day.

Suprarenal Extract.—Von Cyon states, in a preliminary communication in regard to the physiologic significance of the effective substance in the suprarenals, that the extract has a highly stimulating effect on the sympathetic nervous system of the heart and the vessels (accelerants and vasomotors), while it has a paralyzing effect upon the regulator nerves of these organs, the vagus and depressor. Suprarenal extract is consequently a powerful antagonist to iodothyron and the hypophysis.—*Deutsche Med. Woch.*, from *Pflügers Archiv für Phys.*, p. 370.

Dry Treatment of Pus Pockets.—Del Vecchio urges the abolition of the practice of washing out cavities with antiseptic or sterile fluids after evacuating pus. He claims it is directly injurious, and cites a large number of cases he has treated "dry," in which the cure was much more prompt than usual. Even in case of a fistula he merely wipes it dry with gauze and applies a compressing bandage, without drainage or irrigation, occasionally instilling a few drops of some modifying liquid through the mouth of the fistula, left open.—*Gazzette degli Osp.*, September 11.

Conservative Treatment of Wounded Hand.—The main point is to cleanse the hand thoroughly, best accomplished with alcohol and ether, followed with copious irrigation with a stream of hot water, at 50 to 55 degrees C., which has the threefold advantage of being hemostatic, aseptic and warming, thus counteracting the coldness that follows the traumatic shock. It may be necessary to use an anesthetic to make the cleansing as perfect as necessary. Once completed, the wound is dressed with iodoform, or simply sterile gauze, and left untouched for four days, with the hand and forearm immobilized. A wound thus treated heals without a trace of suppuration.—*Martin: Jour. des Pract.*, No. 30.

Strangulated Umbilical Hernia.—Dr. R. Fowler has been enabled to present before the Brooklyn Pathological Society a case of successful operation for the resection of a portion of the small intestine for the above-named condition. The history of the case is not unusual—the ordinary history of vomiting and acute onset, with hardly any rise in temperature, and the strangulated intestine was not situated through the umbilicus, but right along side, as is usual in these cases of acquired hernia. The Murphy button was used and came away on the ninth day. The case calls to mind an earlier one operated on by Dr. S. McGuire of Richmond, in October, 1895. It was a case of strangulated umbilical hernia of forty-eight hours standing, with fecal vomiting, etc. He removed fifteen inches of gangrenous ileum. The patient recovered, the Murphy button coming away on the twentieth day, and the button showed a ring of the intestine at the site where it was placed. In the discussion following the report, Dr. H. B. Delatour offered the following observations regarding the obstacles to recovery after strangulation of hernia of this type. He said: "I think the trouble in strangulated umbilical hernia is, first, that we have the strangulation occurring high up in the intestine, with early appearance of fecal vomiting; second, that we have umbilical hernia occurring most frequently in people who are immensely fat, and in addition to having fat in the abdomen they have fatty degeneration of the heart. Those two points I think enter very materially into the prognosis of the cases—the fecal vomiting occurring early; the retrostalsis pours fecal matter into the stomach when the patient is under the anesthetic, and vomiting occurs; the fecal matter gets into the pharynx, and very frequently portions are inhaled, and may set up either an acute edema of the lunge or be followed by septic pneumonia. I have seen that in a number of cases. In one case upon which it was my fortune to operate, the patient died about ten days or two weeks after operation from the heart conditions solely. The abdominal condition was perfect; the wound had healed by primary union, and the patient died simply from the weakened heart condition." I think the heart was influenced by the anesthetic, and it was the result of the action of the anesthetic on the fatty heart that caused death in that case. Three times before she finally died, within a week, at intervals of twenty four to forty-eight hours, she became absolutely blue from head to foot, and it did not seem possible she could ever recover from the condition, although she did. I have forgotten just what attack she died in, but it was after she had had several. I have operated on quite a number of cases of strangulated umbilical hernia and I recall only one case that permanently recovered.—*Brooklyn Medical Journal*, October.

Journal of the American Medical Association
PUBLISHED WEEKLY.

SUBSCRIPTION PRICE, INCLUDING POSTAGE:

Per Annum, in Advance	\$ 5.00
Foreign Postage	2 00
Single Copies	10 Cents

In requesting change of address, give old as well as new location.

Subscriptions may begin at any time and be sent to

THE JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION
No. 61 Market Street (Occidental Bldgs.), Chicago, Illinois.

MEMBERSHIP IN THE AMERICAN MEDICAL ASSOCIATION.

This is obtainable, at any time, by a member of any State or local Medical Society which is entitled to send delegates to the Association. All that is necessary is for the applicant to write to the Treasurer of the Association, Dr. Henry P. Newman, 100 Washington St., Chicago, Ill., sending him a certificate or statement that the applicant is in good standing in his own Society, signed by the President and Secretary of said Society. Attendance as a delegate at an annual meeting of the Association is not necessary to obtain membership.

On receipt of the subscription the weekly JOURNAL of the Association will be forwarded regularly.

Gentlemen already members of the Association should send their annual subscription to the Treasurer, or direct to the JOURNAL office.

All communications and manuscript of whatever character, intended for publication in the JOURNAL, should be addressed to the Editor, and all communications relative to the business of the JOURNAL, proof-sheet, returned, or in regard to subscriptions, should be addressed to THE JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION, 61 Market Street (Occidental Buildings), Chicago.

Original communications are only received with the understanding that they are exclusively contributed to this JOURNAL.

SATURDAY, NOVEMBER 19, 1898.

CHRISTIAN SCIENCE AND THE LAW.

"Christian science," which may have been prophetically referred to by St. Paul when he wrote to Timothy about "science falsely so called," has apparently made itself amenable to the criminal law in England by the proceedings that preceded and it would seem safe to say directly caused or insured the death of an eminent litterateur. The sacrifice of one valuable life has at last called the attention of the public to the delusions which might perhaps have worked disaster to many more obscure individuals without such effect.

It seems strange that a man of culture, of such penetrative judgment, as some of his writings would imply, as HAROLD FREDERIC should have been a willing victim to what ought to seem to any practically minded man a very transparent delusion. While the fact is hard to account for, assuming him to have been in mental health, something may be allowed for the common and, as it were, very natural affection of the judgment in even any form of bodily disorder. We are all of us apt to be hardly our normal selves under the influence of sickness, and even an educated and thoroughly well-balanced physician, to assume an extreme case, might, under certain circumstances and with certain surroundings, allow himself to be treated by altogether unorthodox and unscientific methods. There is, moreover, a remnant of superstition in all of us, and irrational prejudices and beliefs crop out in the most unexpected quarters. As a scientific investigator who has been amongst the foremost in discussing and developing some of the most important biologic questions, Mr. A. R. WALLACE ought, it would

seem, to be qualified to express a correct opinion on sanitary subjects, but we find him raving against vaccination, a preventive measure that has stood the test of one hundred years since JENNER'S announcement of his discovery, and which has rendered comparatively harmless one of the greatest scourges of our race. With such examples as this, one need not be surprised at any vagaries on the part of the public or of less prominent individuals.

So far as known, there has not been a conviction for manslaughter of a Christian scientist in this country, though occasions for such an event have certainly not been wanting. In so far as the devotees of this delusion actively interfere to prevent the necessary remedial measures and the patient dies in consequence of this, it is hard to see how, with any reasonable interpretation of the law, they can escape its penalties. They certainly in some cases, like that of Mr. FREDERIC, prevented what might and probably would have saved life. The case may be different as regards the standing of Christian science where life is not involved, and we do not see the correctness of the conclusion in a recent editorial in the New York Sun, that, because a court held that contracts for such treatment are valid, the same court would necessarily hold that a charge of neglect and of manslaughter would not lie if death occurred under the care of a Christian scientist who, it could be proven, excluded rational measures that presumably would have saved life. The civil and the criminal sides of the question may differ to some extent, but where the charge of criminal negligence or worse is raised, it would necessarily have to be seriously considered by any court, and it is not easy to see how well-proven evidence of this character could be managed so as to evade the penalty of the law. Judges and juries are fallible, however; some of them may be ardent advocates of Christian science, and it is difficult to say how these facts may distort judicial views and verdicts in special cases.

It will be interesting to follow the proceedings in the FREDERIC case and to see how British justice deals with the matter; the prominence of the victim and the special issues involved will tend to make it a *cause célèbre*. If conviction follows, the status of the delusion in English jurisdiction will be materially affected and it would seem improbable that it could derive any benefit under the plea of persecution if the facts were fairly published and understood. The results of a similar prosecution which has just been instituted in Cincinnati will also be followed with interest by the medical profession and the public generally.

THE CARIBBEAN CLIMATE IN ITS MEDICO
HYGIENIC RELATIONS.

Where so much good, bad, and indifferent has been written about the medical conduct of our late war, it is to be regretted that so little trustworthy informa-

tion is to be found in a short, codified form regarding the climate of the West Indies and the nature of diseases peculiar to Army life.

Excepting the work of LAVERAN on Army diseases and the condensed but comprehensive articles in "Reference Hand-Book of the Medical Sciences," by Dr. IRVING C. ROSSE, on this subject and on the medical topography of the West Indies, but little appears to be written. Even this little, known to comparatively few readers, would not be referred to here but for the present and prospective interest among our people—civil and military—in all that pertains to the Caribbean climate. Outside of the armed forces, the principal element to be affected by the climatic influences of the Antilles are the large number of business men either permanently or temporarily sojourning in our new possessions; the tourist in search of winter sunbeams, and the invalid suffering from pulmonary or other chronic disease.

The physical surroundings of war are anything but conducive to seeing with judicial clearness, and such adynamic concomitants as a diet of salt pork amid stifling heat, diluvial rain, and malaria are assuredly not calculated to give a soldier that rosy view of the radiant skies of immaculate serenity, the flamboyant vegetation, and tropic loveliness of islands that seem lotus-bearing and Eden-like to the well fed and comfortably placed voyager on sudden arrival from the March winds of our bleak New England coast.

The West Indies, usually associated in our minds with rum, molasses, yellow fever, hurricanes, negroes, and general economic, moral and political relaxation are reported to be, and in fact are, very unhealthy, although the islands differ greatly in this respect, the general mortality being influenced by season and altitude, and by the fact of the decedents being indigenes or strangers. The Caribbean summer is a season always attended by mortal maladies to man, beasts, and plants, and by disorder of the elements, which are upset in a frightful manner. With the advent of the hurricane season thunder groans from one end of the horizon to the other, with seismic convulsions, tidal waves, and pathologic phenomena, chief of which is yellow fever. In addition the gravest epidemics of the tropics manifest themselves in the form of malarial fevers, dysentery, and hepatic diseases, which prevail at all the islands at all seasons, and are common to all races. But a compensating factor is the salubrity of the mountain regions—more particularly that of the volcanic mountains. What is known as a climate of impression may be found at a small height. Above 1000 feet yellow fever scarcely ever occurs, the lower sugar-cane lands being its natural abode. At about 2000 feet cooler temperature with more marked delimitation of the seasons is found, along with thermometric and barometric variations of such absolute regularity as to attract attention. A very small number of nycthermal observations suffices to show

the regularity of these movements in an atmosphere free from ochlitic or zymotic contamination.

The mountainous and highly picturesque aspect of the volcanic Antilles, with their blue pyramidal outlines on the horizon, and conical peaks losing thin summits to the clouds, owes this physical configuration to the fact of the islands being nothing more nor less than vast mountains resting on the ocean bed. Bathymetric observations show the deepest water of the Atlantic in their vicinity, being about 5.6 statute miles at "Bronson's Hole," a little north of Porto Rico.

To give systematically the medical topography of most of the islands, particularly those of volcanic formation, would be to repeat many details already familiar to newspaper readers. The characteristics of an active *soufrière*; numerous hot springs; an indescribable richness and variety of bird, insect, and fish life, beautiful scenery; magical and marvelous sunset effects; lovely climate at certain seasons, and botanical remarkableness are so common and striking as to have led DARWIN to speak of Jamaica as "a great, wild, untidy, luxurious hothouse."

The principal climatic observations being likewise more or less matters of common knowledge, it suffices to say that meteorologically there is nothing excessive in the character of the Caribbean climate, which, instead of our four seasons, consists of but two, known to climatologists as *diorique*. Rains, during the season of stifling heat, are the peculiarity of the West Indian region. It is, in fact, the combination of humidity with long-continued heat, rather than its intensity, that marks the climate of the Antilles and causes its insalubrity. Not only does this combination corrupt all kinds of food with great rapidity but hatches out myriads of insects of all species to such an extent as to become repugnant and destructive. Besides, the climate relaxes and impairs the fibers in men and animals, renders them lazy, inert, and phlegmatic, and reduces them promptly to a state of complete atony. In these islands of indolence even mosquitoes are lazy and appear supremely indifferent; fish are not game; imported quadrupeds weaken and degenerate rapidly, the hog alone flourishing. The African negro, transplanted to a sky but little different from his own, has scarcely any physical or moral modification. Flourishing in the Antilles like the green bay-tree, nature is there so much in his favor that after successive generations of mulattoes, children revert to the negro type. More than one-half of the entire population of the West Indies (4,000,000) are negroes, the remainder chiefly mulattoes. Frenchmen do not acclimate and flourish here as they do in Canada under the same isotherm as Denmark, and it is an undisputed fact that families who are not recruited from time to time become extinct in the third or fourth generation. And so we may ascend the zoölogical scale to the Anglo-Saxon, who does not

flourish in an *diorique* climate made tolerable only by the influence of trade winds. Many of our people have seen repeated object-lessons of this fact in the weazen-faced cachectic soldiers who, aside from other unmentionable privations, the criticism of which is outside our province, owe their lowered vitality mainly to such atmospheric vicissitudes as the mid-day sun, the chill of night, and the morning dew of the Caribbean climate.

The question of the disorganizing effect of this climate is therefore one of a highly practical nature, which at present greatly concerns not only our soldiers obliged to serve in the Antilles, but others who may visit them for business and pleasure.

As a matter of fact the subjective bodily effects of the climate are more agreeable than is imagined by persons who have never visited the Antilles. It is well borne by strangers during a temporary winter sojourn; the danger and annoyance therefrom may be much diminished by hygienic measures, and there are healthy and attractive spots where invalids may obtain the advantages that the climate affords.

Notwithstanding the great mortality among our soldiers in the West Indies, it is a notorious fact that much of it was unnecessary and might have been avoided by proper attention to sanitary measures. British regiments have had sad experience in this part of the world, the Twenty-ninth Foot being almost annihilated in Barbadoes by mortal disease in the early part of the present century. However, during a recent service of three years, it is said that none has ever served the same time in the West Indies with so little fatality. The extraordinary good health of the battalion of U. S. Marines lately returned from Guantanamo without the loss of a man from disease, is another striking example of what may be done by proper hygiene.

Doubtless the surgeons of our Army will learn and practice the hygiene of hot climates when they have become emancipated from the thralldom of circumlocution and red-tape, and the narrow ideas engendered by long service at small army posts.

The death-rate of armies has decreased within the last few years, and the general health has greatly improved, but this improvement did not originate with the medical officers. It was brought about by outside influence. In most armies we find the average medical officer about as apathetic and unprogressive as the line officer, who in former days made strenuous objections to the innovation of fire-arms for bows and arrows, and still later, even up to the time of General SCOTT, to the introduction of the percussion-cap in the place of the old flint-lock, and the substitution of breech-loaders for smooth-bores and muzzle-loaders. In saying this it is far from our intention to arraign or criticise a body among whom are many honorable exceptions—men who have advocated the principles upon which sanitary ameliorations are founded. But

it is a matter of history that sanitary reform in the army has been brought about by outside influence. Just as advance in psychiatry, neurology and improved treatment of the insane since the days of PINEL have come from persons unconnected with insane asylums, so have the acts of citizen organizations been of the greatest benefit in removing existing evils and suggesting remedies. This is no less true than the fact that it is impossible to point to any great medical or surgical discovery made by persons connected with armies.

The British army owes its redemption from special sickness and undue mortality to Lord HERBERT, Lord GRAY and FLORENCE NIGHTINGALE, who did so much to relieve the sick and wounded in the Crimea. The sanitary commission of the Civil War contributed much to the comfort of the well and the relief of the wounded; and many poor, fever-stricken patients, whose presence was a scourge and an encumbrance to the Army during our late war, will remember with lasting gratitude the humanizing efforts of the Red Cross.

In spite of the introduction of many reforms and the decreased death-rate of armies, as shown by statistics of the last few years, comparison places army mortality and loss from sickness at a figure still in excess of that of the civil population of the same age living under analogous conditions. Since it would be manifestly out of place to discuss at this present the causes that brought about a mortality of 66.6 per cent. from disease in our Civil War, and the enormous percentage of 88.1 in the Spanish War, it may suffice to say that the diseases influencing the operations of war are mainly those of civil life modified by mesologic circumstances, as typified by the accidents arising from atmospheric or telluric influences, the manner of life and the food consumed. The prevailing diseases of the West Indies, whether among soldiers or civilians, are mostly acute, and at least two-thirds of them being zymotic, are consequently preventable by hygienic or other conditions.

To describe the peculiarity of these diseases and their mode of action would require a repetition of what may be better found elsewhere in works devoted to the maladies of hot climates. It is rather their prevention that most concerns the intending voyager, whether soldier, merchant, or invalid; and in the existing conditions, owing to the absence of sanitary police, it follows that on visiting the Antilles a certain amount of care and circumspection are imperative. The Caribbean climate, at its best, from November to May, is well borne by strangers; and despite the drawbacks of warm latitudes and bad sanitation, one may find Englishmen and other Europeans who have lived many years in the West Indies without sickness. From such old residents many hints of useful nature may be had, which go to corroborate one of the clearly demonstrated facts of preventive medicine, namely,

that with properly enforced hygiene, both public and personal, whether among soldiers or civilians, sickness and mortality in the Caribbean climate may be not only minimized, but reduced to almost that of more favored spots.

THE RELATION OF DISEASE OF THE ACCESSORY CAVITIES TO OPHTHALMOLOGY.

The general practitioner, no less than the specialist, is often puzzled as to the exact cause or causes underlying headaches and neuralgias. While the one is inclined to refer them to the gastro-intestinal or genital tract, the other hastens to ascribe them to alterations from the normal of the various organs that come under his care. Only when both have tried their skill and after apparently righting all existing difficulties in either direction with no relief forthcoming, is there, as a rule, any attention paid to those prolific factors in the etiology of intense cranial pain, disease of the frontal, maxillary, ethmoidal or sphenoidal sinuses. Even the splendid monograph of ZUCKERKINDL on "The Normal and Pathological Anatomy of the Nasal Cavity and its Pneumatic Accessories" directed little attention to these important structures aside from the interest of his immediate followers. In these later times, when the eye surgeon pure and simple is practically an unknown quantity, and the former specialist in eye affections now devotes additional attention to the ear, nose and throat, the surgery of the accessory sinuses falls into the latter's hands as a matter of course.

The cellular spaces contained in the temporal bones have long been recognized as common areas of disease usually secondary to trouble of the middle ear; sometimes the condition is acute, when symptoms of the greatest intensity and danger rapidly develop; more often the process is of slow development, and accompanied by caries of the temporal bone; in both instances a most characteristic symptomatology has been elaborated. In either case operative interference of the most radical kind is indicated and is usually followed by the most brilliant results. The next of the pneumatic sinuses to receive attention was the maxillary, and the scientific work done in this field must ever remain a lasting monument to dental surgery. Of late the remaining accessory cavities, the frontal sphenoid and ethmoid cells, are receiving a prominent place in head surgery. SATTLER (*Medical News*, Sept. 10, 1898) in this connection makes the following interesting statement: "The lesions of the pneumatic spaces of the frontal, ethmoidal and sphenoidal bones are disclosed by the almost uniform presence of characteristic symptoms on the part of the walls of the orbit, its margins or contents, and even if these uncommon cases have not attracted more general attention they, nevertheless, belong to the province of ophthalmic surgery. Unfortunately these cases have not received, even from the majority

of ophthalmic surgeons, the attention they deserve, and only in those unmistakable examples of disease in which these sinuses become the retention-cavities of pus, larvæ, micro-organisms, or tumors, were the indications for rational surgery looked upon as imperative, and even in such cases, unnecessary delay was oftentimes resorted to." It will be noted that "characteristic symptoms" are referred to "on the part of the orbit, its margins or contents;" that is to say, we may have as the result of extension of disease and destructive pressure of contained products, lesions appearing at a distance from the original site of the disease. Under such lesions SATTLER mentions periorbitis and caries of the orbital margin, both following sinus disease. Displacement of the eyeball to either side or forward, producing pronounced exophthalmos, is a not uncommon symptom. As a result of periorbitis or caries we may have fistulous tracts formed which empty themselves, usually externally, far from the diseased origin. "With less frequency we meet with chronic empyema, hyperostosis, exostosis, periostosis, and the growth of osteophytes and exostoses; rarefaction of the cavities with dilatation, in exceptional cases, to enormous proportions; contraction of these spaces either confined to one or several, or as observed in these rare cases, of leontiasis ossea affecting all alike." Surgical treatment dealing with the apparent disease frequently relieves the symptoms but does not cure. It is only by getting at the primary foci and thoroughly eradicating them that we can hope for a permanent beneficial result. It might also be mentioned that it would be wise in the treatment of supra- and infra-orbital neuralgias before resecting the respective nerves to explore with great care the accessory cavities, for these neuralgic affections are not at all uncommon complications of the pathologic process under consideration.

What is the nature of the disease involving these sinuses? In the beginning doubtless streptococcus infection in many cases, either by the blood or more often from extension of nasal diseases, or in the maxillary sinus carious teeth. The pneumococcus is also present at times. In the chronic cases, where caries is a prominent symptom, cases without great pain and in which very little purulent material is formed, are frequently tuberculous from the outset; though indeed acute cases may be accompanied by caries and necrosis as the result of closure of all avenues of exit and a resulting harmful pressure.

Not infrequently we find no signs localizing the disease to any particular cavity, the only symptom indeed being intractable headache usually located in the frontal region, but may be radiating. In such patients the frontal sinus may be the one at fault; on opening the sinus everything at first glance appears normal, and it may be only by the careful use of the probe or curette that granulation tissue of uncovered bone is detected. That this apparent trivial condi-

tion has produced the symptoms is evidenced by the fact that drain of the cavity is followed by a disappearance of the terrible pain. Nor can these people be said to have been afflicted with hysteria and that any operation would have cured them: the large majority were by no means strangers to the operating table. SATTLER, by his timely article, written as it is by one of vast experience, can not but direct even more attention to this line of work than it is now receiving, and that is not inconsiderable. With the progress made of late doubtless the subject will receive deserved notice, which is sure to bring about a rational and scientific treatment.

THE LIMITATION OF OPERATIVE TREATMENT OF EPILEPSY.

In the discussion of the operative procedure of epilepsy, one very important fact has failed to command the attention it deserves. Because an epileptic seizure is localized in its onset and course, it by no means argues that the epileptic lesion is a gross one or one to be benefited by operative procedure. We may have non-traumatic partial epilepsy, or what has been described by FERE as parcellar epilepsy or monospasm. These partial epilepsies may, and generally do, tally with grand mal fits in all other respects aside from their peculiar muscular spasm.

Again, because the epileptic fit has a leisurely and well-marked order of invasion in the convulsion, it does not necessarily prove that a focal disease is at the beginning of the fit. Many grand mal epileptics, apparently idiopathics, come to autopsy with no visible local cause for this systematic order of invasion. Even various forms of localized paralytic phenomena, motor and sensory, may occur in such cases without discoverable lesion in the brain. Facts like these should deter operative procedure in such cases. Further tests are necessary before we trephine them, as only harm can come from meddling in an operative way with such an epileptic's brain.

What, then, does the order of invasion prove to us? Simply that one part of the cortex requires less irritation to provoke a discharge, or has less power of internal resistance in maintaining its normal status, and takes the lead in the epileptic fit. Frequently we see one of these seizures delayed by mechanical means, until another part, usually secondarily involved, begins the muscular spasm. We are inclined to think a much narrower limitation of operative work among epileptics would result if the above facts were borne in mind.

The hereditary instability of the cerebral cortex of epileptics has not been given the attention of late years that it really demands. We can not refrain from placing ourselves on record as opposed to the radicalism in the present-day studies of the etiology of epilepsy. Some of the studies devoted to eye-strain and its correction, satirically referred to by one of our

prominent neurologists as "tampering with eye muscles," is too absurd to call for special comment. GOWERS, one of the greatest living English authorities in nervous diseases, has said that the so-called reflex epilepsies are exceedingly rare.

To this same category may be assigned similar reflex disturbances in nasopharyngeal, urethral and many gastro-intestinal cases. In regard to this latter class of cases, which have probably given more aid to the upbuilding of the toxic, autotoxic and dynamic causes of epilepsy than any other phenomena in the disease, we notice that CLARK of the Craig colony, in his studies of the aura of epilepsy, has recently called our attention anew to the important fact that such symptoms from the digestive tract are most frequently due to a nerve disturbance originating primarily in the brain, and like any other aura or warning, referred to the periphery along sensory paths. Frequently such sensations may precede, follow or take the place of an attack. In this latter instance it exists as an aborted attack of epilepsy, common to the experience of many epileptologists.

Again, malassimilation, constipation and chronic intestinal catarrh may equally be caused by defective tone of the cerebral nervous system. We do not doubt that visceral symptoms most frequently accompany epilepsy as an effect of the disease and not as the cause. In such cases we should not consider toxicities as the one great thing to be studied and possibly eliminated, but the hereditary instability of the cerebral cortex of the epileptic. In our minute examination of the organism of the epileptic by the aid of chemistry and pathology, we are liable to overlook the autonomy of the nervous system as a whole. How often does the clinical observer declare on paper, in examination of a case of epilepsy, that there is "no cause in hereditary factors," and yet in looking at the case in a critical manner is able to see little indefinable and intangible frayed ends of inherited factors which come under the cognomen of no well-marked condition or disease.

At best, the study of the excitant of an epileptic attack will give us the degree of instability only and can not help to solve the far greater problem as to what that instability really consists of. The real chemico-psychologic change in the nerve-cell during an epileptic fit may never be known: at least by methods at present in use it seems impossible. As we have before remarked editorially in these columns, the necessity of approaching the pathologic physiology of epilepsy by means at present in use for the study of the brain in experimental psychologic laboratories can not be too urgently insisted upon. But it must not be studied in a psychologic light alone. Although we have received a rebuke from the great VIRCHOW in referring to a man as a "biologic unit," yet we can refer to it in this manner when we wish to express that the whole organism is to be studied.

and not a single apparatus. We must endeavor to bring to our aid in epileptic studies the accumulating facts of cytology in development and inheritance to further the study of the multitude of "biologic units" in man, and especially upon the units of the cerebral cortex.

INTERNATIONAL MEDICAL STATISTICS.

In 1894 an international committee of military medical men of which Dr. JOHN S. BILLINGS, then lieutenant-colonel and deputy surgeon-general on the active list of our army, was chairman, met at Budapest, Hungary, and formulated a series of international statistical tables with the view of enabling a ready comparison of the prevalence and fatality of disease in the various armies to be made. These tables were formally adopted, and since 1895 Surgeon-General STERNBERG has embodied them in his annual reports. Chiefs of the medical departments of other countries have not been so prompt in getting up their statistics in this comparable form. In the JOURNAL of May 21, 1898, we noted the publication of the first tables of this kind issued by the British Government, for the year 1896. We have now to record the publication of similar tables from the Netherlands for the year 1897 in the form of an octavo pamphlet from the *Imprimerie Nationale* at La Haye.

A few items taken from these tables will show the facility with which points of interest requiring investigation or explanation may be detected. The bracketed figures given below are those of our own army for 1897, obtained from the office of the surgeon-general. The recklessness of the United States soldier is manifested by the excessive number of accidental and violent deaths, as well as by the ruptures and the cases of alcoholism.

The mean strength of the Army of the Netherlands was 27,458 [23,843] during the year, and the admissions to sick report 1450.7 [1186.6] for every thousand men present. A total of 85 [86] deaths occurred among these, or 3.09 [3.14] per thousand living; but these deaths do not include 8 [10] suicides nor 6 [54] deaths by accident or violence. The amount of sickness was equivalent to 10.8 [13.1] days for each man in the army, and the average duration of each case was 13.9 [11.07] days. Arranged by months, September had the lowest admission rate, 73.6 [December 90.57]; March the highest, 177.2 [October 106.87]; August the lowest death-rate, .07 [July 0]; May the highest, .42 [June .46]. Of special maladies and groups of maladies skin diseases occasioned the largest number of admissions to sick report, 87.8 [75.37] per thousand men for the year, the cases having an average duration of 9.1 [8.3] days. Acute bronchitis came second with 52.7 [58.55] per thousand. The malarial fever rate was only 8.9 [80.69], notwithstanding the malarial reputation of the "Low Countries," sustained historically by the breakdown of the

Walcheren Expedition. Forty-six [80] ruptures were reported during the year, the patients in 28 [65] cases having been cured and returned to duty. No case of acute alcoholism nor of delirium tremens [666 cases, or 27.93 per thousand men, with 2 deaths] was reported during the year; but there were 29.3 [55.49] admissions per thousand for gonorrhea, with an average duration of 32.7 [22.19] days, and 6.7 [12.79] for syphilis with an average duration of 34.5 [36.7] days. Only 16 [174] cases of typhoid fever were reported, but of this small number 7 [8] were fatal; 193 [65] cases of pneumonia of which 14 [4] ended fatally and 122 [59] cases of consumption, 16 [7] fatal. The advantages of these International Tables are obvious.

CORRESPONDENCE.

The Vital Statistics of the War.

WASHINGTON, D. C., Nov. 12, 1898.

To the Editor:—In a communication in the JOURNAL of October 29 I directed attention to the unsubstantial basis on which an editorial writer in the *Philadelphia Medical Journal* made a demand, on behalf of the medical profession, for an explanation of the fact that the ratio of death from disease to death from all causes was greater in the Spanish War than in the Civil War. The pressure of official business was so heavy that I was unable to discuss the conclusion admissible from the figures given by the journal cited, or to give some statistics which I am confident would have been regarded with interest by the members of the AMERICAN MEDICAL ASSOCIATION, but this I propose now to do.

The statement was made that death from disease formed 66.6 per cent. of the total mortality in the War of the Rebellion and 88.1 per cent. in the Spanish War. Accepting these figures at their face value, for I have not considered it worth while to verify them, we learn simply that more men were killed and fatally wounded out of every hundred who died in the service of their country a third of a century ago than in the recent war. This we can readily understand, when we recall the fact that on July 21, 1861, when the first serious clash of arms took place between the North and South at Bull Run, Va., nearly as many men were wounded and nearly twice as many killed as in the whole Spanish-American War. This one fight was but the beginning of a series which ran the list of battle fatalities up to the terrible total of more than ninety thousand deaths. It may, however, be claimed that the difference between the ratios in question was due, not to a greater prevalence of battle casualties in the former war, but to a greater prevalence of fatal disease in the late war. This can not so readily be accepted as an explanation, although a great deal has been said, written and printed about the sickness at Santiago, Chickamauga, Alger and other camps where our volunteer troops were aggregated. We may not assume that the sickness which affected our young men was more extensively disseminated or more deadly than that from which their fathers suffered in the earlier war, because, as a matter of fact, we know that it was not so. Time has dulled the National memory of what happened in the days of the Civil War. Perhaps the remembrance of those times remains fresher with myself than with most others, not because I was with the troops in the field until the end came at Appomattox, for many others had as full an experience of army life in the field, but because it afterward became my duty and my high privilege to spend over three years of my life in studying the records of sickness, while compiling the third part of the medical volume of

the "Medical and Surgical History of the War." That history is on our shelves, and by referring to it we may at any time find out how diarrhea and dysentery, typhoid fever and malarial diseases swept through our camps and sent their thousands to the hospitals and to their graves. We may also compare the deaths recorded by the medical officers of those days with the deaths recorded by the medical officers of the present time, and should we do so we would find overwhelming testimony to the effect that any differences discovered in the percentage of deaths from battle, casualties, and from disease, are not due to the greater prevalence and fatalities of disease in the recent struggle, but to the number of sanguinary battlefields of the Civil War.

In April, 1861, President Lincoln called for 75,000 volunteers, but it was not until after July 22, when his call for 500,000 was made, that we had armies comparable in size with those recently in existence. Beginning, then, with July, 1861, when we had medical reports from regiments aggregating only 69,118 men, and including August, September, October and November, five months, we find recorded a loss by death of 3075 men in the reports sent in by medical officers, from an average strength present of 177,690 men, or 17.31 deaths out of every thousand men during that period of five months. More deaths occurred than were reported, for some surgeons failed to send in reports; but the probabilities are that, had the missing reports been forthcoming, the deaths would have continued to have the same proportion to the reported strength.

In April, 1898, President McKinley called for 125,000 men and later for 75,000, which, with an increase in the regular Army and the immune and other special regiments, made a total of over 270,000 men. Beginning with May, 1898, for which month we have medical reports in the office of the Surgeon-General of the Army from regiments aggregating 151,685 men, and including June, July, August and September, five months, we find on file a loss by death of only 1715 men reported by medical officers, in an average strength of 167,168 men, or 10.21 deaths out of every thousand men during that period of five months. More deaths occurred than were reported, for some surgeons have failed so far to send in reports, but the probabilities are that were the missing reports forthcoming, the additional deaths would be associated with a proportionate increase of the strength. This proportion of deaths to a strength of 270,000 men would give 27.70 as the total of reported and unreported deaths.

According, then, to the testimony of every medical officer who has placed himself on record then and now, we lost in the five months of the war with Spain 10.21 men out of every thousand reported present by medical officers serving with them, and in the first five months of the War of the Rebellion, 17.31 out of every thousand similarly reported present. This is interesting, but it is still more so, if we look a little more into the details of these reports. During the month of May last the death-rate was low, .46; it was somewhat higher in June, .70, or the equivalent of an annual rate of 8.4 per thousand. In July it rose to 2.15 for the month or the equivalent of an annual rate of 25.8 per thousand. In August, owing to the rapid spread of typhoid fever in the camps, and to the broken down condition of General Shafter's Corps, it reached 4.08, equal to an annual rate of 48.96, such as was common in cities before the era of municipal sanitation. The War Department immediately put forth its energies to remedy this condition of affairs and with such efficacy that the death-rate in September fell to 2.45. If it be claimed that this falling off was due to the fact that the typhoid infection had done its worst and that, irrespective of all sanitary measures, the death-rate would have fallen owing to the exhaustion of susceptible material, we have merely to consider what was the history of our Civil War camps subsequent to November, 1861, when, as I have stated, the number of deaths had already

amounted to 17.31 per thousand of the strength present. In that month of November the rate was 4.27, or somewhat more than our recent maximum of August last; but the next month, December, showed no sign of decrease, for 1578 men died, or 4.69 per thousand. During January, 1862, the ravages of disease continued, 1664 men having been swept away by death, or 4.84 out of every thousand of those present. In February the rate was 4.79 and in March 6.08. In April the culmination was reached when 3331 deaths were reported, constituting a death-rate for the month of 8.42 per thousand, a rate twice as high as that reported from our camps in August last.

This is a startling record. Mortality from disease reached its maximum in the camps of our Civil War only at the end of ten months, if we count from July, 1861, or at the end of twelve months, if we count from May, 1861, when 47.56 men had been buried out of every thousand of strength present, or, to put it otherwise, the maximum monthly mortality was reached only after ten or twelve months of suffering, during six of which the mortality was greater than that of the disease which did so much harm in August last. In that month the country became excited over the hysteric utterances of yellow journalism, with 4.08 deaths per thousand, and the morale of the Army became broken by making the volunteer believe that never in the history of armies had men suffered from disease as he and his companions had suffered. Yet thirty-seven years ago the flower of the manhood of this country, after months of deadly losses, suffered in April, 1862, more than twice the loss incurred in August last, and instead of going home on sick furlough they girded up their loins for the attack on Richmond, by way of the Peninsula.

Respectfully,
CHARLES SMART,
Deputy Surgeon-General, U. S. A.

Bicycling.

SEATTLE, WASH., Nov. 5, 1898.

To the Editor:—In the JOURNAL of October 29, you have something to say about the ill effects of bicycle riding, and among other things is mentioned the long-since prophesied ill effects on the female pelvis, by way of distorting or contracting the same, and rendering childbirth more difficult. A little further on you say: "We are not aware that the obstetricians are having any greater difficulty in delivery than formerly." And why should they? The gentleman who had prophesied that the bicycle would have a serious effect on childbirth had a mistaken idea of the entire proposition. While bicycle riding may deform the pelvis, it will have little or no effect as regards the ease of childbirth. And why? For the simple reason that "bike" riders do not have babies. Where or who is the physician that has attended a "bike" rider in confinement? Will the female rider throw aside her wheel long enough to have a baby, let alone to rear a respectable sized family? The bicycle is a nuisance and a curse instead of a blessing. While it may have a beneficial effect physically upon a few, yet the ill effects upon the many ten thousand times overbalance it. The deaths and the maiming from wheel accidents—almost equal perpetual war. The injury to heart and kidneys of thousands must be added. Then what of the nuisance of the machines on street and sidewalk everywhere? In the public thoroughfare they are a constant menace to teams and footmen, and as there is no bounds to the impudence and effrontery of these wobblers, they presume also to usurp the sidewalks in most cities, whether permitted or not by law? Think of such ungovernable vehicles approaching foot-people on sidewalks every few rods as they proceed, at a speed of twelve to fifteen miles an hour, jingling their little bells, warning you to jump aside or be run over or maimed! And when one steps aside there is no telling but the cranky thing will make a dive for his solar plexus or coccyx, since all sorts of wobblers presume to usurp the walks that were in

times past, before we became so civilized, supposed to be for footmen only.

The advent of this horrid means of locomotion is an instance in which the inventive genius of man has overtopped itself, or at least he has invented a machine that causes a great many individuals to be overtopped. Here in Seattle, bicycle riders pay a license and are permitted by law to ride on the sidewalks, so footmen step aside as they whiz by or take the chances of suddenly converting the momentum of one of these machines and its rider into heat, light and electricity.

A. C. SIMONTON, M.D.

Conservative Treatment of Intestinal Occlusion by Internal Electricity.

OAK PARK, ILL., NOV. 15, 1898.

To the Editor:—A criticism of an article under the above caption, credited to the able pen of Dr. J. R. Pennington of Chicago, appears in the JOURNAL of November 5. As the author of said article I respectfully request that you publish my answer in your columns.

1. The critic calls me to account for not giving Dr. Boudet credit for his original work and untiring effort. However, I did state in quotation from Dr. Larat that Boudet had treated fifty cases with 75 per cent. of cures, a better percentage of cures than is shown by any other practitioner, even including surgery.

2. As to electrolysis: He says to use the author's electrode, the oxychlorid of the metal used may have an indescribable effect on the tissues, and attempts to overcome this difficulty by using a disc of soluble "copper, carbon, zinc, gold or platinum." Of course he does not mean a solid disc of gold or platinum. The expense is prohibitive. Consequently I fail to see his advantage over me, as it is as easy to plate my electrode as it is his disc. His deductions on electrolysis, however, are overdrawn. With the current used in this treatment it would be so slight as to be harmless, unless the treatment was carried on indefinitely.

3. The Doctor criticizes me, in very poor taste, on the "Code," for in the same breath he describes minutely, with an accompanying cut, an instrument that is named "Dr. J. R. Pennington's Colon Electrode." As to the merits of his instrument I am doubtful. The coil (which he is pleased to call a flexible cable), covered with vulcanized India rubber, is no better as a conductor than an ordinary copper wire, and of no more use as a mechanical device for introducing the rectal tube. This deduction is from the fact that the coil is smaller than the internal diameter of the soft-rubber colon tube, and does not support the caliber. Consequently, the tube will kink and double up, and is no better than the soft-rubber rectal tube, and can not generally be introduced into the sigmoid flexure. As to the general similarity of the two rectal tubes under discussion (his and mine), I will simply refer you to the cut in his article, and the description of my tube which I give in my original article. From this comparison the reader may draw some very interesting conclusions as to Dr. Pennington's general source of information on the subject.

R. P. JOHNSON, M.D.

Rush Monument.

PHILADELPHIA, NOV. 4, 1898.

To the Editor:—As the committee on Rush monument are desirous of having a thorough organization of the profession in the States and Territories, will you please urge immediate attention to the request for the appointment of a committee-man for each State and Territory? Thus far very few have notified me of any selection of a representative.

Yours very truly,

W. B. ATKINSON, M.D.

Foreign Body in the Ear.

CINCINNATI, OHIO, NOV. 6, 1898.

To the Editor:—Mrs. H. brought her son, 9 years of age, to consult me in regard to his left ear. He had been treated for earache, deafness and ringing in the ear by a physician for the past month, but could not get any relief. Good illumination showed the auditory canal to be normal, but what at first sight I supposed to be the membrana tympanum, showing as it did the cone, or pyramid of light, did not present the outlines of the ossicles. Instead of probing I used the politzer inflation on that side, and again examined the ear and found that I had dislodged the supposed drum, which was a foreign body tightly impacted against the membrana tympanum. A syringe full of warm sterilized water brought away a circular concavo convex piece of mother of pearl (the larger end of a small button). When in the ear it presented the concave surface.

CUNDELL JULER, M.D.

PUBLIC HEALTH.

Hay Fever in Switzerland.—A collective investigation of the etiology and therapeutics of hay fever has been commenced in Switzerland by Dr. A. Wyss of Geneva, according to the *Schweiz. Corr. bl.*, No. 19.

Hygiene in Schools.—The recent French Congress for the Advancement of Science passed resolutions urging the teaching of hygiene by a physician in all the schools above the primary grades.

Sanatoria for Convalescents.—The city of Paris has recently entered into possession of a much-needed asylum for convalescents, a chateau at Mary-sur-Marne, which, with its large grounds, was bequeathed by its late proprietor for the use of women who have undergone surgical operations in the Paris Hospitals. There is already room for forty.

Quarantine Convention Delegates.—Dr. A. J. A. Egan, secretary of the Illinois State Board of Health, and Dr. John B. Hamilton of Chicago, are delegates for Illinois to the Quarantine Convention at Memphis, November 17, 18 and 19. Dr. A. R. Reynolds of the Chicago Department of Health is the delegate for Chicago, and Dr. J. C. Sullivan of Cairo the delegate for that city.

Sanitation in Mexico.—Information from Mexico City, November 5, is to the effect that the government is taking measures for carrying out the sanitation of Mexican Gulf ports. It is believed there that when the American Government completes the reconstruction of the sewerage system of Havana and cleans out the bay, with moderate care in Mexican Gulf ports, yellow fever can be stamped out.

The Bubonic Plague.—United States Consul Hurst, at Vienna, dispatches to Washington, D. C., that three deaths have occurred from bubonic plague, and that there are now only six cases in the entire city, and these are all hospital attendants. Mr. Hurst adds that the infection of immigrants is improbable, ample protection against possible infection of suspects, or in fact any who have been in contact with infection, being provided.

Support of Illegitimate Children.—The new Code to go into operation throughout the German Empire in 1900, provides that the man who has had relations with the mother of an illegitimate child between the 182d and the 302d day before the birth of the child, is to be summoned before the justice of the peace and compelled to assume the pecuniary obligation of paying a certain small amount annually for its support until it is fourteen. If there are several men they must raise the amount collectively. There is no question of paternity. The relations are merely those of debtor and creditor, and the proceedings in the court are private. The child belongs to its mother, but

the certainty of its support prevents infanticide and desertion, and places the burden where it belongs. The man can also adopt the child if he wishes, even without marriage with the mother, and confer upon it all the legal rights of a legitimate child. Somewhat similar legislation has proved very effective in Great Britain, and the *Semaine Méd.* is urging its introduction into France.

Yellow Fever.—The increase of yellow fever at Havana has caused the United States Government to seriously consider the problem of landing an army of unacclimated volunteers to take possession of that city a few weeks hence. Nothing toward cleaning and disinfecting can be done until the American troops are in complete control. The original occupants are less capable and less disposed than ever to be sanitarians, now that their departure is so near. The few weeks of delay may prove a sacrifice of many lives.

Santiago Healthful.—Gen. Leonard Wood, governor of the military department of Santiago, under date of November 1, authorizes the statement that during the last sixty days there has not been a case of yellow fever. With warm commendations of the Red Cross Society for their continuous help and for their supplies, which have been effectively distributed by officers of his own appointment, he warns against fictitious tales of suffering and asks that hereafter all the applications be referred to him for endorsement. It is now expected that much before the close of the month the staff of the yellow fever hospital will be abolished. It has been maintained merely to care for a few suspected cases, and with the cooler weather its further services are not needed.

Military Sanitaria for West African Troops. The King of Belgium has evinced an alert attention to the sanitary well-being of his Congo State troops. One of the greatest drawbacks to the expansion of European rule in West Africa is the deadly climate and the difficulty of dealing satisfactorily with fever-stricken troops. If they remain at their posts they run every risk of succumbing; if they are brought back to Northern Europe the sudden transition from a tropic temperature to the chills and damps of their own countries may also prove disastrous. King Leopold, therefore, has in view the establishment of a sanitarium within reasonable touch of the Congo territories, which shall be at once genial and free from malaria. Northwest Morocco was at first suggested, but a second and decidedly better scheme has presented itself and is in a fair way of being carried through. The Canary Islands are considerably nearer the west coast than is Morocco, and lie in the direct route of the Congo steamers. Their climatic conditions are too well known to medical men to need any remarks. A medical commission has left Antwerp for Las Palmas to choose the site for the sanitarium and the King has placed 25,000 francs at the head of the subscription list by which the necessary funds are to be raised. It has always been the custom of our military medical service to provide hospital steamers for the reception of fever cases among our troops whenever large numbers have been on active service in malarial districts, but the establishment of a permanent sanitarium in a climate such as that of the Canaries, within easy reach of our West African dependencies, is certainly a plan well worthy the consideration of the authorities of the Royal Army Medical Corps. English troops are constantly quartered in those districts, and many valuable lives might be saved to our army by such an institution.—*London Lancet*, October 22.

Local Inspection of Water-Supplies.—Dr. Thresh holds the opinion that it is the exception to find either public or private water-supplies adequately protected. In fact, he would take a still more serious view of the situation, and say that it is the exception to find such supplies protected at all, except in the crudest manner. Dr. Thresh's remedy is legislation and education. Both are powerful agents, and to the latter unequal-

fied support may be given. There is room for discussion as to the best legislative means to be adopted, as was recognized by the parliament when it refused to insert the clauses introduced by the local government board in certain private water bills, as being of the nature of limited legislation on an important subject. Dr. Thresh suggests, as a basis for future legislation: 1. That sanitary authorities should have power to close any shallow well which can be proved to be liable to pollution. 2. That no shallow wells shall in future be made until the site selected has been approved by the medical health officer for the district. 3. That sanitary authorities should be empowered to make by laws having reference to the construction of such wells. That control of water supplies by an authority is necessary, all will admit, and that such control should rest to a large extent with the sanitary authority, is doubtless desirable for many local reasons; but that it would be wise to vest in that officer the ultimate control of the water supplies in his district we venture to doubt. The water supply of a district is ultimately a physiographic question; and geologic formations are not coterminous with administrative districts. A central water authority is the only solution of the control question. On it should rest the responsibility of opening wells, while the local sanitary authority might wisely be entrusted with their enforced closure. Most hygienists will agree with Dr. Thresh when he says, "I am strongly inclined to think that all public supplies, whether owned by sanitary authorities or water companies, should be under the supervision of some higher authority."—*British Medical Journal*.

SOCIETY NEWS.

Washington Microscopic Society.—At the regular meeting of this society, held November 8, the program was "Abstract of Foster Lecture on the Physical Bases of Psychic Events."

Columbia Historical Society.—At the meeting of the society held in Washington, November 1, Dr. Samuel C. Bussey read a very interesting paper on the history of daguerrotypy in Washington.

Southern Kentucky Medical Association.—The semi annual meeting of this Association was held at Russellville on November 2. Dr. M. E. Alderson of Russellville was elected president and Franklin chosen as the next place of meeting.

Wyoming State Medical Society.—The second regular meeting of the society convened in Rock Springs, November 1, under the presidency of Dr. R. Harvey Reed. The program was full and the papers elicited a good discussion. The society passed resolutions condemning the Anti-vivisection Bill now pending in the Senate, also the granting of a patent on diphtheria antitoxin to Behring, and recommending the establishment of a National department of public health, with a physician as cabinet officer at its head. The society was entertained by Drs. Reed and Freeman and the citizens of Rock Springs, and the meeting will do much to organize and unify the medical profession of Wyoming. The following officers were elected for the ensuing year: President, Dr. R. Harvey Reed; first vice-president, H. J. Maynard; second vice-president, G. G. Verbyck; third vice-president, E. E. Levers; secretary and editor, E. Stuver; treasurer, C. H. Solier. The next meeting will be held in Laramie City on the second Tuesday of October, 1899.

Washington Obstetrical and Gynecological Society.—The two hundred and eighty-seventh meeting of this Society was held November 4, at the residence of Dr. Van Rensselaer. Dr. H. B. Deale read the essay of the evening, entitled "Constipation in Infants." He limited his remarks to young breast-fed infants, and recommended the cure of the infant through hygienic and dietetic treatment of the mother. An interesting discussion followed, participated in by Drs. Acker, Sprague,

Smith, Winter, H. L. E. Johnson, Balloch and S. S. Adams. Dr. Stone reported a case of death from sepsis, after an operation for ventral fixation. He also presented the specimen and gave the history of a case resembling abdominal pregnancy. The Fallopian tube and tumor were referred to the microscopic committee.

Philadelphia Pathological Society.—At a meeting of this society, held November 10, Dr. George E. de Schweinitz presented several mounted specimens of sarcoma of the choroid and sectional drawings, together with micro-photographs and stained specimens of metastatic carcinoma of the choroid. Glioma of the retina was also spoken of. Dr. de Schweinitz thought his specimens of metastatic carcinoma of the choroid the twenty-seventh on record. Dr. J. H. Jopson read a paper, and presented a specimen showing epithelioma of the penis. He stated that a superficial section, obtained previous to operation only, showed the growth to be papillomatous, but deeper sections obtained afterward revealed its malignancy. Dr. Joseph Sailer read a paper, and presented specimens of a species of worm he had discovered and identified as being the louse of *strongylus pneumonia* in sheep, an epidemic disease which has proven to be very malignant in certain regions of the State. Dr. John M. Swan presented a case of anomalous position of the cecum, showing that its position had been maintained in the epigastric region during the life of the patient.

Third Pan-American Medical Congress—Postponement.

INTERNATIONAL EXECUTIVE COMMISSION OF THE
PAN-AMERICAN MEDICAL CONGRESS.

OFFICE OF THE SECRETARY, CINCINNATI, NOV. 5, 1898.

My Dear Sir:—I have the honor to announce that in April, 1898, I received from Dr. José Manuel de los Rios, chairman of the Committee on Organization of the Third Pan-American Medical Congress, a request that, in consequence of the then existing rebellion in Venezuela, no definite arrangements be made at that time relative to the meeting of the Congress previously appointed to be held in Caracas in December, 1899.

The following communication relative to the same subject is just at hand:

CARACAS, Sept. 25, 1898.

Dr. CHARLES A. L. REED, Secretary of the International Executive Commission, Cincinnati, Ohio:

Dear Sir:—After having sent my communication dated April last, I find it to be my duty to notify you, that although the considerations pointed out in it have already ended, our country has been scourged by smallpox, which has taken up all our physicians' activities and time, depriving them of going into scientific works. And, as that state of mind of our people and government after such calamities as war and epidemic, would greatly interfere with the good success of our next meeting, I beg leave to tell you, in order that you will convey it to the International Executive Committee, that our government and this commission would be grateful to have the meeting which was to take place in Caracas in December, 1899, adjourned for one year later. I am, dear Doctor, yours respectfully,

THE PRESIDENT,

(Signed)

DR. JOSÉ MANUEL DE LOS RIOS.

In accordance with the request of the Government of Venezuela and of the Committee of Organization, the Third Pan-American Medical Congress is hereby postponed to meet in Caracas in December, 1900.

For the International Executive Commission.

CHARLES L. REED, Secretary.

Medical Society of Kings County.—The appellate division of the supreme court of New York has reversed the mandamus procured by the oldest medical society having its headquarters in Brooklyn, by which it was relieved from the payment of taxes on real property. The mandamus having been appealed by the Board of Assessors, the latest ruling will require that the society shall pay the bills for taxes, amounting to several hundred dollars. Judge Woodward, who wrote the decision for the appellate division, said that the theory of the law disfavored exemptions from taxation, except in that class of cases

where the property is to be put to some use calculated to minimize the expense of government. The society grounded its petition for exemption on the establishment by it of an organization for mental improvement and for certain educational and charitable purposes. This, according to the decision of the court, is most commendable in the physicians making up the medical society, but it does not entitle them to exemption from taxation under the laws of this State. There is no allegation that the society is organized for the exclusive purpose of carrying out any of these objects, and if there was it would still fall short of the requirements. There is no claim that the purpose of the society is to improve the morals of either men or women, or that it is for religious, missionary, hospital, patriotic or historic purposes. In other words, the society is performing no service of a character calculated to relieve the burdens of government more than a thousand other mutual associations or corporations designed for the promotion of the individual development of its members. It is in effect a medical club house, where the members of a single profession meet for "mental improvement" and such incidental benefits as flow from association and co-operation of effort.

Washington Medical Society.—At the meeting held November 9 Dr. D. S. Lamb presented the heart from a 13-year-old boy, and gave the following history: While climbing a fence the child accidentally thrust a needle into the heart. In extracting the needle a portion remained. For two days the patient suffered no evil effects; at the end of that period he fainted and suddenly died. Autopsy showed a portion of the needle in the heart just below the pulmonary valve. Death was caused by hemorrhage and pressure. He also presented a case of ulcerated carditis with abscess of spleen. The heart showed vegetations in the aortic and mitral valves. Organism causing disease not known. Dr. J. Taber Johnson presented a calcified myoma of the uterus, which he removed from a patient aged 61 years; she had had the tumor for twenty years. Three years ago she had a sudden abdominal enlargement with febrile symptoms; several gallons of fluid were drawn off and the mass connected with the uterus removed. The mass had undergone calcareous degeneration and resembled a fetal head. Dr. Fry presented a dermoid cyst in the right ovary. The patient was 38 years of age, and was supposed to have suffered from floating kidney in its normal position. The left ovary was also found to be cystic. The dermoid contained hair, teeth and bones. The other ovary contained a similar kind of fluid, and was supposed also to be dermoid. Dr. Fry read a paper entitled "Antistreptococci Serum in Puerperal Sepsis." Dr. Fry was one of a committee appointed at the last meeting of the American Gynecological Society to investigate the use of serum in the treatment of puerperal sepsis. He referred to the Paris Maternity, where in a case 8 c.c. of serum were used on the first day, with no effects. The second day 8 c.c. better, and the third day 25 c.c. was used, followed by improvement and convalescence. Of 119 cases reported 77 were cured, 42 died—35 per cent. mortality—consequently this mortality is higher than the modern antiseptic treatment. He considered the treatment indicated only in cases of streptococci infection, and bacteriologic investigation necessary. Of 46 inquiries, 14 were favorable and 35 unfavorable. Barton Cook Hurst has no faith in it. R. C. Norris uses it in all cases, and considers his life saved by it. Munde, three cases, is pleased. E. P. Davis, total failure in many cases, but great success in others. It is called for when free flushing fails. E. P. Reynolds says it controls chills. Dr. Fry thinks it has a limited field: 1, the cases must be of streptococcus infection; 2, stage of disease is important—too late when streptococcus is in the blood, consequently should be given early. If local, the patient suffers most from ptomaine poison. Serum is of benefit when given in doses of 5 to 10 c.c.; bad cases require larger doses. Fatal cases have rapid pulse, low temperature and uncontrollable vomiting. He thinks curetting harmful in streptococcus in-

fection, except when necessary to remove diseased tissue. Curette valuable only in sapremia. He cited two cases: In one, abortion, patient had delirium, cough, temperature 105; serum given and transfused; grew worse and died; laparotomy showed necrosis of uterine wall, supposed to have been punctured with an instrument. Concerning the use of thyroid extract in uterine fibromata, he claimed it reduces tumor and controls hemorrhages. He reported four cases: two young women with hemorrhage and two after menopause; all improved. Long-continued use of drug causes anemia and palpitation.

NECROLOGY.

LOUIS BOWER, M.D., St. Louis, Mo., died in New York City, November 5, aged 84 years. Born in Stettin, Germany, of poor parents, he put himself through school by teaching, and soon after his graduation was appointed district surgeon to look after the poor and needy. The district of Stolt sent him to the lower house of the Prussian Reichstag, and there he championed the cause of the democrats to such an extent that he was sent to prison, but while in jail was re-elected. Before he took his seat he discovered that the Government feeling was such as to necessitate his flight, and he settled in London. After his flight the German Government passed sentence on him and decreed that he should spend eleven years in prison. This sentence was in force until 1870, when a general amnesty was extended to all political refugees. In 1854 he settled in Brooklyn, N. Y., and there helped found the Long Island College Hospital. In 1869 he located in St. Louis, and there founded the College of Physicians and Surgeons, but after three years gave it up. Shortly after, he again started it and was its Dean until three years ago. Probably his best known work is "Orthopedic Surgery." He also translated many German works into English.

A. M. MILES, M.D., Harvieland, Ky., died on the 2d inst. of consumption, after a long illness. He had recently removed to that place from Shelby County.

PERRY H. BENSOOTER, M.D. of Peely, Pa., died at Lexington, Ky., of typhoid fever, November 4, on duty as contract surgeon at Camp Hamilton. He was a graduate of Jefferson Medical College, and 30 years of age.

E. L. BETTERLY, M.D., Wilkesbarrs, Pa., died November 3, aged 67 years. During the Civil War he was surgeon of the One Hundred and Sixty-fifth N. Y. Infantry, and later major of the same regiment.

D. R. DEWEY, M.D., North Adams, Mass., died November 5 from disease contracted at Chickamauga, while on duty as an army physician.

JOHN HELM, M.D., N. Y. University, 1861, died November 7 at his home in New Brunswick, N. J., after a long illness. He was a veteran of the Civil War and had been a member of the Board of Education for eleven years.

CARL ENGLEHARD, M. D., Chicago, November 6, aged 64 years.—J. St. Pierre Gibson, M.D., October 31, aged 66 years.—F. S. C. Grayston, M.D., Huntington, Ind., November 6.—John H. Kappel, M.D., Fort Wayne, Ind., coroner of Allen County, October 31, aged 28 years.—J. M. Marsh, M.D., Delphos, Ohio, November 2, aged 35 years.—Fred. Merrick, M.D., Barclay, Md., November 4, aged 36 years.—J. H. Mullens, M.D., Waco, Texas, October 30.—Abraham H. Robinson, M.D., Concord, N. H., October 31, aged 85 years.—G. Rutz, M.D., Port Townsend, Wash., November 1, aged 68 years.—Christopher C. Sharp, M.D., New York City, November 5, aged 77 years.—Frank P. Thompson, M.D., St. Louis, Mo., November 5.

MISCELLANY.

Tabetic Atrophy of Optic Nerve.—Silex found forty-four syphilitics out of fifty-four cases of tabetic atrophy of the optic nerve. Twelve had undergone a thorough specific treatment; eight had been treated for years; fourteen with inunction cures and the rest with pills. He concludes that even the most thorough treatment is not always able to prevent the development of this affection. He found all treatment of the atrophy ineffectual; electric, potassium iodid, strychnin, argemum,

etc., administered in all kinds of ways. The only possible means to retard the development of the affection is with strengthening therapeutics to tone up the organism, especially the nervous system.—*Vienna klin. Rund.*, October 30.

Gasserian Ganglion.—In the *Am. Jour. of the Med. Sci.* for November, Keen and Spiller present "Remarks on Resection of the Gasserian Ganglion," with the following method for the preservation of the eye in that operation: Either immediately before or at the close of the operation disinfect the eye and sew the two eyelids together by two or three stitches, near the margin, drawing together only the middle of the lids. This leaves the two ends open sufficiently, first, for washing the space between the lids and the eyeball with a warm boric acid solution, to wash away any mucus, and also leaves enough space to observe the cornea when the patient looks strongly to one side. This occlusion of the lids should last not less than four or five days, when the stitches may be cut and the eye immediately covered with a Buller shield, i. e., a watch-glass held in place by means of either a circular fenestrated disc of rubber plaster or by four separate pieces of plaster. The shield should be used from ten days to a month after the operation.

Large Excision of the Omentum.—Montini describes, in the *Gazz. d. Osp.* of September 11, a case of strangulated hernia with threatening symptoms, in which the hernia only contained a small normal intestinal loop, with a very large amount of gangrenous omentum, which he was compelled to excise. The patient made a good recovery, and has shown no disturbances from adhesions to date, although the excised portion of the omentum was about 40 cm. square.

Adherent Retroposed Uteri.—Pryor (*Med. News*, October 29) enters the pelvis at its lowest point, through the posterior cul-de-sac, in three cases, and finds suturing necessary only when large portions of the ovary are removed, opening small sprouting vessels. He considers that this method allows conservatism as in no other method of operation. Following thorough preparation of the vagina the uterus is curetted and then, selecting the fold behind the cervix which marks the reflection of the vagina, he enters Douglas's cul-de-sac. After digital exploration the incision is spread laterally until the posterior retractor can be introduced. The uterus is then "lifted up into the abdomen by the curved trowel and several gauze pads are inserted into the pelvis." The patient is then put in Trendelenburg's position, when the operator is enabled to see and treat the adnexa as desired. Drying the pelvis, after the operation, iodoform gauze is introduced just within the incision and "these and the uterus replaced *en masse*, the cervix being forced as high as the vagina will permit," and gauze packed lightly around the cervix "until that portion of the vagina which is above the levator ani muscle is almost filled. A stout roll of gauze is then made, varying in thickness and length to suit the width of the vagina" and inserted above the levator ani fibers; in front of the cervix, its ends in the lateral pelvic cavities; the cervix is thus kept anchored.

Rupture of Symphysis Pubis During Labor.—In the *Am. Jour. of Obstet.* for October, De Lee reports two cases, one where the child was delivered spontaneously, the other after prolonged and difficult extraction. Later, in the latter, operation revealed a large abscess around the pubic joint, which was ruptured, the ends of the symphysis being three-quarters of an inch apart and much evoked.

Anthrax of the Lungs.—Schottmuller observed two cases in persons employed in sorting rags and wools, in which infection had evidently occurred by inhalation of the germs. The diagnosis is difficult, but is indicated by severe cyanosis such as only accompanies pronounced disturbances in compensation, and also by severe collapse after slight exertion. There is usually a pleural effusion but no certain indications of pneumonia.

The very high temperature at first falls below normal in the course of two or three days. The prognosis is very grave.—*Munich Med. Woch.*, No. 39.

Composition of Diphtheria Toxin.—P. Ehrlich states that besides the essential toxin in diphtheria poison there are other substances very much less toxic, "toxoids," which are important, however, as they bind the antibodies the same as the essential toxin. As a diphtheria bouillon culture stands, the toxin diminishes while the toxoids increase. He classifies the toxoids as: protoxoids, which have a stronger affinity for the antitoxin than the genuine toxin; syntoxoids, which have the same affinity as the toxin; and epitoxoids, which have less affinity. He considers the latter a primary product of the bacillus and not a transformation product of the diphtheria toxin, and calls them "toxones." These toxoids and toxones are not simple substances, but can be subdivided into what he calls proto, deuterio and tritoxins. His research proves that in the diphtheria toxin molecule there are two independent atom-complexes. One is haptophorous, that is, it binds the antitoxin; the other is toxophorous, the cause of the specific toxic effect. Experiments on frogs disclosed that the first exert their effect even when cold, but that the toxophorous require warmth before they can affect the cells. This difference in time explains the incubation period. There seems to be a further possibility that the protoxoids are able in certain circumstances to effect a direct cure by forcing the toxin out of its combination with the elements of the tissues, by means of their stronger affinity for it.—*Deutsche Med. Woch.*, No. 38.

Army Medical Examining Boards.—Several boards of army medical officers are or have been recently in session for the examination of medical men for position or promotion. One board, convened at the Army Medical Museum, examined medical officers of the army for promotion in accordance with the requirements of the existing law. Another board for the same purpose was convened in Santiago, Cuba, to obviate the necessity of sending the officers concerned home for examination. A third board, to which greater interest attaches, is examining candidates for appointment as assistant-surgeons at the Army Medical Museum Building. This Board consists of Colonel Dallas Bache, assistant surgeon-general; Majors J. C. Merrill and Louis A. La Goode, surgeons U. S. A.; Major Geo. E. Bushnell, surgeon U. S. Vols., and Captain E. L. Munson, assistant surgeon U. S. A. There are fifteen actual and also some prospective vacancies to be filled, but it is said that the Board will probably succeed in filling them, as the professional qualifications of the candidates are above the average. Another board was convened in the same building, November 2, consisting of Major Walter Reed, surgeon U. S. A., Major Victor C. Vaughan, division surgeon U. S. Vols., and Captain George D. De Shon, assistant-surgeon U. S. A., for the examination of acting assistant-surgeons. Until recently the current work of the Army Medical Department was so great and the need for assistance so pressing that contracts were made with medical men on the strength of the letters of recommendation which they had filed with their applications for position. Now, however, it appears that candidates for these positions will have to demonstrate their professional qualifications before getting an assignment to duty.

For Female Contract Nurses in the Army.—Surgeon-General Sternberg has issued a Circular defining the status, duties, and privileges of contract female nurses as follows:

Contract and Duties.—The contract which is made by the Surgeon-General with a female nurse for Army service is for an unlimited period. In signing this contract and taking the oath of office a nurse is understood to promise that she will perform the important duties entrusted to her with unwavering devotion to the welfare of her patients and with the dignity of demeanor which is essential for Army service. Reports of each nurse are sent to the Surgeon-General, and on these reports action is based.

Pay.—While under contract a nurse receives \$30 a month salary; payable either on pay rolls or vouchers. While nursing at a hospital she receives also her lodging, board and laundry of uniforms. Expenses incurred for these things by a nurse will not be refunded.

Uniform.—No uniform for nurses has as yet been prescribed, but for the present a nurse is expected to furnish and wear such dresses, aprons and cape as are usually considered suitable.

Chief Nurse.—If the surgeon of a hospital so requests, the Surgeon-General may appoint a chief nurse, whose duty it shall be to look after the welfare of all of the nurses in the hospital; to see that they are comfortable and that they receive attention when ill; to assign each to her specific duty and see that the hours of such duty are strictly kept. She is also expected to have supervision of the general department of the nurses and to perform such other duties as the surgeon may direct, but not to undertake nursing herself.

Traveling Under Orders.—After signing the contract a nurse is subject to military discipline and must promptly obey any order given her. When traveling under orders she must not stop on the way. She must not, under any circumstances, leave her post or take any journey without written authority from the Surgeon-General or from the surgeon under whom she is serving. When traveling under orders she will be furnished in advance with transportation. This means an order for her railway ticket and sleeping-car berth, which are exchanged by her at the station for regular tickets.

Leaves.—A nurse will not receive pay for time absent from duty unless given by the surgeon—in writing—a sick leave or leave of absence "with pay." This must be for a specified time, one week before the expiration of which the nurse must report in writing to the Surgeon-General for orders, unless she already has orders to return to her former place of duty. Should her services not be needed at that time the Surgeon-General may annul her contract. While on leave with pay the nurse is entitled to commutation of rations at the rate of 25 cents per day. To obtain this she must, when she returns to duty, apply to the surgeon, who will endorse her papers of leave and forward them to the nearest commissary.

Leave of Absence.—When a nurse is granted leave of absence at her own request, she does not receive pay for the time absent, unless the surgeon grants—in writing—a "leave with pay," which can not exceed ten days or be allowed soon after entering the service. As she is not traveling under orders she does not receive transportation.

Sick Leave.—In case of sickness contracted in the line of duty, a nurse is entitled to medical attendance either in her quarters or at the nearest available army hospital. But if she prefers to return home, or to some other hospital, the surgeon may grant a sick leave with pay (for thirty days). If the surgeon also gives her written orders to proceed to her destination, she will then be entitled to transportation, as explained above. In such a case another nurse may, if necessary, be ordered to accompany her, and transportation furnished her also. If unable to return to duty at the end of the sick leave, a certificate from the attending physician stating this fact, and the probable date when the nurse will be fit for duty, must be forwarded to the surgeon granting the sick leave or to the Surgeon-General, if she has no station. This certificate is sufficient to cover absence for the term specified therein. Bills for medical attendance can not, under the regulations, be allowed.

Transfer.—Transfers from one hospital to another are ordered only when the necessities of the service require it. The preference of a nurse is consulted whenever possible, but she is expected to remain at the hospital to which she is assigned so long as her services are needed there. Nurses who go to Porto Rico or Cuba are expected to remain at least six months, if their services are satisfactory.

Annulment of Contract.—The contract of a nurse may be annulled at any time by the Surgeon-General or by his direction. A nurse is not expected to request such annulment before the expiration of two months, unless able to give satisfactory reason therefor.

Transportation, as above defined, is given on annulment of contract, except when "for misconduct or neglect of duty."

Transportation will be to place of making the contract, except that when made at the place of duty it will be furnished to the place designated in the contract as her residence.

The War Investigating Committee.—The following is the testimony of the volunteer medical officers of the army before the Committee of Investigation, at the sessions held in Chicago, Nov. 7-10, as reported in the daily press:

Dr. Lewis Schooler of Des Moines, Iowa, was the first wit-

ness. From June 7 to July 17 Dr. Schooler was stationed at Camp Thomas as chief surgeon of the Second Division, Third Corps. Questioned by Dr. Conner, he said that during the time he was there the sanitary conditions in the hospital were not very good; that the sinks in the whole division were bad, owing, principally, to the character of the ground, and that the discipline was rather lax.

"At the opening," said Dr. Schooler, "there were practically no facilities for the care of the sick; we were short of medicines and had no apparatus by which the stewards could prepare the medicines we had. The regimental hospitals, all but one or two, were as poorly supplied with medicines as the division hospitals. Requisitions were made for more, but they were generally disapproved at the camp headquarters. I do not know that the requisitions were absolutely turned down, but they were frequently reduced. It was in reference to the quantity rather than to the articles themselves that difficulties arose. I think the supply department issued stores according to its ability, but not always with promptness. It had certain hours for issuing supplies, and at other times nothing could be obtained.

"There was a scarcity of beds in the hospital, but I never saw a man lying on the ground. I went through the hospital every morning and inquired of every man able to speak if he had been neglected in any way. Very seldom was there a complaint from a man who was really sick. Sometimes they complained about the lack of medicines. Occasionally patients recovering from typhoid fever complained about the diet, just as any convalescent fever patient would do at home. So far as I know there was never any patient neglected to such an extent that his chances of recovery were materially reduced. At one time practically half our nursing force was sick or in the guardhouse for insubordination."

Dr. Conner—Why was not a demand made by somebody that better or more nurses should be sent to that place?

Dr. Schooler—I don't know. I wrote the surgeon general once, protesting against the difficulties of securing supplies. Part of the blame rested upon the quartermaster's department.

Asked to give, in as few words as possible, his opinion about the general conditions at Camp Thomas during the time he was stationed there, Dr. Schooler said:

"In the first place, the quartermasters and surgeons could not agree as to the number of tents we should have. Colonel Lee contended that we were limited to a certain number of tents, seventeen I think it was in the beginning. We afterward prevailed upon him to give us twenty-one. His contention was that he could not issue tents beyond the prescribed number. I think he based the number of tents upon 150 patients, and when the number of patients became greater we could not make him understand that we had to have more tents. It was his refusal to increase the number of tents that made the overcrowding.

"The lack of medicine, the lack of trained nurses and the lack of a sufficient number of surgeons was a material difficulty. One cause of the prevalence of sickness in the camp was that we had three regiments who came there with a great deal of sickness—the First Mississippi and the First and Second Arkansas. There was much typhoid and dysentery in these regiments. I think the quartermaster's department was largely responsible for the great sickness; the medical department (that is the supply department) was also responsible for some things. Then we lacked facilities to make reports on—did not even have stationery. We were told all the time that reports must be made."

Dr. Conner—So far as you know, was there on the part of any medical officer or surgeon any wilful neglect in the care of the sick?

Dr. Schooler—No sir. The great difficulty was in obtaining supplies, and I think the hitch came between Colonel Hartsuff and the medical supply department.

Dr. Schooler said he never knew Dr. Hubbard to force medicine down a patient's throat, as had been charged, although he thought that might sometimes have been necessary if the patient were delirious. He said he never knew of patients in any considerable numbers being kept in regimental hospitals until they were moribund and then sent to division hospitals. For the successful care of the sick, Dr. Schooler considered the division hospital far superior to regimental hospitals.

"I left July 17," he said, "before any epidemic had set in. In my judgment the responsibility for the continuance of the conditions there does not rest upon the division surgeons. If there is any responsibility it rests somewhere else. The surgeons in our division were hard working and faithful."

In regard to the water-supply at the camp, Dr. Schooler stated that he did not think any of the surgeons in his division considered the water fit to drink. There were not enough

teams at the disposal of the officers to enable them to bring sufficient water. When asked for his reasons why he considered the water unfit to use the doctor said that upon several occasions he had visited the ground around where the supply was taken from the river and felt convinced from what he saw that much of the prevailing disease was caused by the negligence of the policing department in allowing the soldiers to go at will through the woods situated along the banks of the stream. He gave this as a reason for many of the cases of typhoid fever existing in the camp.

Another feature which contributed largely to the sick list in the opinion of the Doctor was the laxity shown in issuing passes to the men and allowing them to visit other camps. "Fifty per cent. of the sickness," said the Doctor, "would not have been in existence had the men not been allowed to leave Chickamauga Park on passes." He gave as his opinion that the medical officers were hampered too much by officers of higher rank, but who had no medical training. In regard to division hospitals the Doctor said:

"I think there should have been a hospital at Chattanooga where patients could have been taken who were going to be sick any length of time. The division hospital was never intended for this class of patients." When questioned as to the lack of nurses, the Doctor said he thought both the nurses as well as the officers were overworked.

In many cases one nurse was compelled to take charge of twenty, thirty and sometimes forty patients during the night, which was too much to expect of one person. No blame could be attached to the doctors, as they would start out in the morning on their rounds of duty and would be on duty until late at night. When questioned as to the complaints about starvation, the Doctor said that a great many of these were entirely unwarranted. As to the general conditions surrounding the patients in the hospital, the Doctor gave it as his opinion that the average soldier was just as well treated there as he would have been at home, excepting, perhaps, in the line of bathing. In this direction he possibly might have received more attention, but this only affected the comfort of the soldier and did not necessarily affect the mortality in camp.

Dr. Nicholas Senn said:

"When I reached Chickamauga there were 40,000 soldiers encamped there. There were already a good many cases of typhoid fever and the disease was spreading rather rapidly. I do not believe it would have been possible to isolate the patients so as to keep it from spreading. Chickamauga was an ideal camp for a short period, but for a prolonged camp I considered it dangerous. The typhoid fever was brought there, it was spread by flies, and the sewerage and sanitary arrangements were imperfect. These conditions made disease inevitable. The sinks were properly dug, but they were not properly policed. The hospital arrangements were as good as could be expected."

Dr. Senn was next questioned about conditions at Santiago and Siboney. He said hospital supplies were scarce and the medical force was small; yet the materials at hand were so well utilized that the number of deaths was comparatively small. The supplies, he said, could not be landed for want of lighters. Speaking of the treatment of sick soldiers brought North on the *Relief*, he said:

"The *Relief* was a model hospital ship. I came North on her, and there was space for 250 passengers, while she carried only 147. The men were well cared for. We had six female nurses and eighteen male nurses, and the nursing arrangements were as perfect as possible. The sick had the best care it was possible to receive on a ship. When the *Relief* went back to Porto Rico I went with her. She carried everything needful in the way of hospital supplies, and indeed was a relief ship. At Porto Rico the sick had better care than those in Cuba, as the supplies were more generous. I accompanied the ship North again when the sick she carried were landed at Montauk Point.

"Do you know whether any transport left Porto Rico carrying 170 sick men, with no medical supplies?" asked Dr. Conner.

"If such was the case I never heard of it."

Speaking of the conditions of Montauk Point, Dr. Senn said for a short camp it would have been all right, but the location was such as would foster disease where it was occupied for a long time. Regarding hospital arrangements he said:

"The hospital construction at Montauk was the marvel of this short war. I don't believe any war, recent or remote, can furnish an example of such perfect hospital accommodations furnished in such a short time. The equipment was luxurious. The government gave us everything we asked for in the way of delicacies, and the Red Cross spent \$2000 a day there. The sick soldiers lived in luxury. Of course there were times

when there was congestion, but this could hardly be avoided, as ships were landing men nearly every day."

Dr. Senn said the only criticisms he had to make were a lack of co-operation between the quartermaster's and the medical departments, which delayed supplies, and the detailing of medical officers to executive work, when their attention would have been better directed to surgical work.

Dr. Milo B. Ward of Kansas City, Mo., who was a brigade surgeon at Camp Thomas from July 12 to September 10, when asked as to the condition of the hospitals, said that there was a great lack of medicine, only some of the simplest being on hand. He said that the food would have been all right had it been properly cooked. He said he knew of several cases where the patient was allowed to lie on the ground the whole day and also during the night before taken to the hospital.

Seventy-five per cent. of the patients were on cots and the other 25 per cent. were on stretchers on the ground. Sometimes at first some of the men were put on the bare ground, but within a few hours they were always put on cots or stretchers.

Dr. Conner—"What was the reason that the Second Division Hospital of the Third Army Corps had the worst reputation of any hospital during the war?"

Dr. Ward—"The first reason, in my judgment, is that the hospital had for its corps surgeon a man who never paid any attention to it whatever. His name was Hoff. The next reason is that the man in charge of the hospital, the division surgeon, seldom visited the hospital or paid any attention to it. His name was Jenney. The next reason is that there were not enough doctors at any time to take care of the patients without overworking the doctors and making them too ill to get out of bed.

"The stores that were necessary were not available from the army supplies. Milk and ice were obtained from other sources. Had it not been for the Red Cross some of the soldiers would have starved."

Dr. Conner—"Who was responsible for this?"

Dr. Ward—"For the condition of the camp, first, the man who insisted that the camp was perfect, and that the hospital was well run. That man was General Boynton. He was responsible for keeping the army there when that army ought not to have been kept there. The want of supplies was due to the fact that the quartermaster's and commissary's department were not hounded enough."

"What was your opinion of the location of the hospital?" was then asked the Doctor.

"The location of the hospital was extremely bad, in my judgment," he replied.

Dr. Wm. Cuthbertson of Chicago was then called to the stand. "After locating our camp," he said, "we immediately made details to provide for sanitary conditions. The surface soil was shallow, and on digging three or four feet we would strike water. The ground was perfectly non-absorbent and the sinks being used by the men would become in a filthy condition in a short time."

He then went on to show how that, whenever a rain occurred, these sinks would become flooded and thus result in an unsanitary condition. This was the beginning of the trouble. When a requisition was sent in for quicklime with which to disinfect the camp there was no supply of that material. The Doctor then went into details to show how the medical department was handicapped by the lack of many necessary articles for the perfect sanitation of a camp. The question of regimental hospitals as compared with division hospitals was then brought up. It was the opinion of Dr. Cuthbertson that in theory the division hospital was superior, although from his experience he thought that in many cases the regimental hospital was better for the men, as they were then under the charge of physicians who were more liable to take a personal interest in the patient.

Dr. G. A. Smith of Clinton, Iowa, was appointed a brigade surgeon and served from July 14 to September 10. He was in charge of the hospital of the Second Division of the Third Army Corps at Chickamauga. He was questioned at considerable length.

Dr. Smith—When I assumed my duties at the second division hospital on the 14th day of July I found a shortage of tents and cots. The patients in the hospital were crowded on account of shortage in tents, and some of them were lying on the ground on account of lack of cots. There was no provision made for feeding the sick other than the rations issued to the soldiers in the regular service, except such as were brought in by charitable organizations, principal of which were the Red Cross Society and the National Relief. In the pharmacy there were at that time no intestinal antiseptics, although the commanding officer informed me when I made a requisition for these that he had made repeated efforts to get them. The

pharmacy at that time—and, indeed, until it was ordered closed and I turned the stores over to the Government on the 9th of September—never had any proper equipment for doing pharmaceutical work. There were no scales to weigh with and the hospital stewards used a board for a tile and an ordinary jack knife for a spatula. There were no pill-boxes or powder-boxes. The stewards dispensed tablets and pills in any paper they could secure, and they were carried to the wards in that shape, and owing to the prevalence of dampness at night they would become by morning a sticky mass not fit for use.

The medical supplies did improve after the 1st of August, he said, but up to that time there had been a great scarcity of supplies. The water was bad too.

General Dodge—How about the water?

Dr. Smith—The water that was furnished for the use of these hospitals up to August 1 was that taken from the pipe line from Chickamauga creek, and it was so full of sediment that it was simply slush and was not water.

There were no floors in any of the hospital tents at the time I reported for duty at that hospital. The first tent was floored soon after the middle of July, although some were not floored until long after that. The floors in the tents of the Fifty-second Iowa, the First Maine and the Fifth Missouri were all laid after the troops had left the park and were never occupied by the soldiers, and never had cots placed in them. In fact, I might state that the floors were laid after orders had been received to pack goods preparatory to leaving for Anniston.

In regard to nursing in that hospital, we had no trained nurses. All the nursing was done by orderlies, and many of them were densely ignorant, and when I was in charge of the wards of the Second brigade I had two men who could neither read nor write, and three men who did not know the meaning of "A.M." or "P.M." when written.

In regard to the sinks, disinfection and drainage: right back of the tents of the Second brigade there was a cesspool which contained most of the water from the camp, and that remained a stagnant pool until some time in August.

In speaking of the infection of the camp, Dr. Smith said a large part of the typhoid germs was carried around by the flies which invaded the grounds. The water-supply, he said, was not contaminated by sewage carried into it from the camp, but mainly by an inorganic sediment which acted as an irritant on the men's digestive organs and caused, in many cases, dysentery and other intestinal diseases.

Dr. Smith said he regarded Dr. Milo B. Ward, who testified the day before, as a very competent and a very conscientious man, and would not doubt any statements Dr. Ward might make as to conditions at Camp Thomas.

Dr. Smith—I once wrote a report to the Surgeon-General, but I think it never got any farther than General Boynton's office. I was asked by General Boynton and Major Jenney to withdraw it, as it might get me into disfavor personally, but I told them there was nothing in it that I wished to withdraw.

Gleanings.—Acute infection, simulating a cerebro-spinal meningitis in a woman of 61, no syphilis, probably of intestinal origin, causing an abscess of the liver and extensive thrombosis in the vessels of the pia mater of the spinal cord.—*Nordiskt Med. Ark.*, xxi, 2.—Ernest has succeeded in cultivating a bacillus from a case of pseudo-melanosis, affecting the liver, spleen, aorta and kidneys, which reproduced the disease and is evidently the etiologic factor. The bacillus is straight or slightly wavy, from 2 to 16 μ in length, slightly enlarged at one or both ends, motile, liquefies medium and generates an abundance of hydrosulphuric acid. This fact tends to confirm an old theory that attributed the production of pseudo-melanosis to the presence of free iron sulphid in the organs affected.—*Arch. f. Path. Anat.*, clii, 3.—Success of creosote carbonate in children's pulmonary infections, non-caustic and not disagreeable to take.—Cure of large angioma of the lower lip with four treatments with bipolar electrolysis.—*Presse Méd.*, October 29.—Case of complete dislocation of the foot without fracture (except of the bicycle), exclusively on the talocrural joint, the tip of the foot turned inward, the sole outward, the outer edge of the foot in front. Easy reposition in narcosis.—Extirpation of the spleen on account of traumatic rupture, in sixth month of pregnancy, which continued undisturbed to normal delivery.—*Vienna Klin. Woch.*, October 27.—Jonnesco reports 23 splenectomies, all but one for malarial hypertrophy. One died during the operation; seven since from

various causes. The rest much benefited. He agrees with Laveran that the spleen is the receptacle of the hematoozon. Leukemia is the only contraindication to the operation.—*Bulletin de l'Acad. de Méd.*, October 25.—Case of nasal secretions streaked with blue, reported by Molinié.—*Rev. de Laryng.* October 29.

Washington.

COLUMBIAN UNIVERSITY HOSPITAL.—The college hospital was formally opened for the reception of patients November 1, on which day the dedication ceremonies were conducted. The college building is located within one hundred feet of the medical department and will accommodate thirty patients. Beds have been endowed by Drs. W. W. Johnston, Middleton F. Cuthbert, Gardner G. Hubbard and the First Baptist Church. The following constitute the hospital and dispensary staff: Surgery, Drs. J. Ford Thompson, W. P. Carr, John Van Rensselaer, John Wellington and Frank R. Hagner; medicine, Drs. W. W. Johnston, D. W. Prentiss, G. N. Acker, G. Wythe Cook, T. A. Claytor, B. L. Hardin, Thomas Dowling; obstetrics and gynecology, Drs. A. F. A. King, H. L. E. Johnson, J. W. Bovee, H. S. Medford, V. B. Jackson, J. E. Jones and E. E. Moree; diseases of the eye, Drs. D. K. Shute, W. K. Butler, F. K. Newell; diseases of the throat and ear, Drs. C. W. Richardson, F. P. Morgan; diseases of the skin, Drs. H. C. Yarrow, R. B. Carmichael; diseases of children, Drs. T. E. McArdle, Frank Leech; orthopedics, Dr. A. R. Shands; diseases of the nervous system, Drs. D. W. Prentiss, E. L. Tompkins, Sterling Ruffin, A. L. Lawrence; genito-urinary, Drs. T. R. Stone, W. T. Birch; clinical laboratory, E. A. de Schweinitz and J. E. Carrol; pathology, Drs. Walter Reed, U. S. A., and L. W. Glazebrook; superintendent, Miss A. G. Odell; resident physician, C. S. White. Donations are earnestly solicited from Baptists.

ASSOCIATED CHARITIES.—The report of the Associated Charities for the past month shows that fifty-three investigations were made of applicants for free medical treatment; forty one were applicants for treatment at the Central Dispensary and Emergency Hospital, and of this number thirty-one were approved, eight were refused and two were found to have given false addresses. Twelve applicants for treatment at the Woman's Clinic were investigated, all of which were found worthy of free treatment.

REPORT OF MEDICAL SUPERVISORS.—The first annual report of the Board of Medical Supervisors of the District, organized under the Act of 1896, has been submitted to the District Commissioners, and shows that 1047 licenses were issued to physicians who were registered previous to the operation of the act; 86 were examined by the board for license, of which number 42 succeeded, 12 failed and 26 were recommended for future examination. Ninety-five licenses were issued to midwives, under the law exempt from examination, and the board remarks, "most of these were given under protest, as the ignorance of the applicants made it impossible for them to comply with the regulations regarding report and registration of diseases." The board recommends that provision be made at one of the hospitals for the education of midwives, as, in the present state of social development, the services of midwives are necessary, but an unskilled midwife is dangerous and her ignorance a menace to public health. The board recommends that a special officer be detailed to investigate alleged violations of the law by midwives and physicians. Six applicants applied for license to practice and were examined; E. L. Lemerle, Wm. H. Hughes, Jr., and Frederick H. Mohart passed successfully and three failed.

HONORABLY DISCHARGED.—Drs. Auther Snowden and John W. Bayne, majors and surgeons of volunteers, have been honorably discharged from the service. Acting Asst. Surgeon James R. Church, the hero of the Rough Riders, has returned on furlough and will probably enter the medical service of the regular army. Dr. Church has earned his promotion, and is one of the best equipped surgeons of Washington. He was formerly one of the surgeons of the Central Dispensary and Emergency Hospital, and filled his position with marked distinction.

HEALTH OF THE DISTRICT.—The report of Health Officer Woodward for the week ended November 5 shows the total number of deaths to have been 126, of which number 83 were white and 43 were colored. The principal causes of death were: Nervous diseases, 20; circulatory, 16; respiratory, 26; intestinal, 1. There were 6 fatal cases of typhoid fever and 5 of diphtheria. At the close of the week there were 148 cases of diphtheria and 119 cases of scarlet fever under treatment. There were 245 births, of which 115 were white and 130 colored.

PHYSICIAN TO THE POOR.—On the recommendation of the health officer, the District Commissioners appointed Dr. Vergil B. Jackson physician to the poor, to serve during the absence of Dr. Battle.

WOMAN'S CLINIC.—At the annual meeting of the Woman's Clinic, held November 5, the following officers were elected: President, Mrs. Emily Sherwood; vice-presidents, Dr. D. S. Lamb and Miss Eva Simonton; secretary, Mrs. M. F. Case. The old board of directors, the consulting staff and standing committee were re-elected. Drs. Heiberger and Norris were appointed drug committee for the ensuing quarter. The annual report shows 562 new cases treated, 4866 visits made and 6500 prescriptions compounded.

CIVIC CENTER.—At the annual meeting of the Civic Center, held November 7, Dr. W. W. Johnston read an interesting paper on the bad effects of school life on the hygiene of children. Dr. Nordhoff Jung addressed the society on the effect of school life on teachers. Dr. Samuel S. Adams spoke on some of the so-called school diseases. Dr. George M. Kober read an address entitled "Many of the Causes of So-called School Diseases."

Cincinnati.

APPOINTMENT.—Dr. Otto Geir has accepted the position of junior assistant physician at the Worcester Insane Asylum, Worcester, Mass.

LAURA MEMORIAL HOSPITAL.—This gift of Mr. Alex. McDonald of this city to the Presbyterian Hospital, was formally opened November 1; patients were admitted the next day.

ACADEMY OF MEDICINE.—At the regular meeting, November 7, Dr. Joseph Eichberg exhibited a number of irregular, greenish, non-faceted concretions which had been sent to him under the supposition that they were gall stones. The patient by whom they were passed was supposed to have been suffering from gall-stones and had been given a pint of olive oil; these concretions were the result. By chemic and microscopic means he had succeeded in proving that they were composed entirely of fatty matters. He also thought that these fatty concretions so often passed after the exhibition of a large amount of olive oil, were frequently mistaken for gall-stones. Dr. Henry Bettman read a paper entitled "Some Suggestions as to Diet in Diseases of the Stomach." The principal argument insisted upon by the author was that patients afflicted with stomach trouble, or supposed to be so afflicted, were habitually put upon a too restricted diet. Many of them were being practically starved to death, and the lessening of nutrition only aggravated the condition of the stomach. No dietary could be put down for any one class of patients; every patient is a law unto himself. He believed in the old saw "that one man's meat is another man's poison," and thought that the diet should be restricted only in that which the patient is unable to digest. Those who took part in the discussion were Drs. Zinke, C. R. Holmes, Kiely, Fackler, Oliver, Jones, Eichberg, Johnston, Langdon, J. Louis Brown, Marcus, and M. Brown.

Louisville.

QUARANTINE COMMISSIONERS.—Governor Bradley has appointed Dr. J. M. Mathews of Louisville and Dr. J. B. Kinaird of Lancaster as delegates to the National Quarantine Convention, in Memphis, Tenn.

MEDICAL STAFF.—The medical staff of the Home for Friendless Women has just been organized as follows: Ewing Marshall, chairman; Henry E. Tuley, secretary; Louis Frank and Frank C. Simpson, visiting physicians; Wm. Bailey and Preston B. Scott, consulting physicians; S. G. Dabney in charge of eye, ear and throat department.

GODSHAW.—Dr. C. C. Godshaw, on October 31, was shot by a colored man-servant, the ball entering the abdomen and penetrating the stomach and duodenum. He was able to walk into his house, was shortly removed in an ambulance to St. Joseph's Infirmary, where a laparotomy was done by Dr. A. M. Vance, within fifty minutes of receiving the wound. His condition the next morning was excellent.

BELL.—Capt. Austin Bell of Hopkinsville has been appointed surgeon-major of the Third Kentucky regiment.

ORPHANS' HOME.—A meeting of the board of managers of the Louisville Baptist Orphans' Home was held November 2. Dr. J. B. Marvin is president of the board and physician to the Home. In the past twenty-nine years the Home has cared for 1059 children, of whom one-third came from Louisville. There have been only seventeen deaths in the history of the institution and no fatal accident has ever occurred.

MORTALITY REPORT.—The health officer's report shows a total of 215 deaths during October, against 222 deaths for the corresponding month last year. Consumption caused 19, pneumonia 15, inanition 14 and old age 10. There were 332 births and 58 marriages.

BOWERS.—Dr. Henry Bowers, the physician from this city who is seeking fortune in the Klondike, has written a friend that his prospects are very bright for amassing a fortune. He is practicing medicine, has opened a drug store, and in connection with this is operating a vapor-bath house, which is prospering. He states that the miners are suffering largely from scurvy.

Hospitals.

By the will of R. M. Raab of Burlington, Iowa, who died recently, the Michael Reese Hospital, Chicago, will receive \$1000 and the Old Folks' Home \$500. Other bequests are: Burlington Hospital, \$1000; Mercy and St. Francis Hospitals, also of Burlington, \$500 each; Orphans' Home of Atlanta, Ga., \$1000; Orphans' Home and Hospital of Baltimore, \$1000; Philadelphia Hospital, \$1000; Old Folks' Home, Richmond, Va., \$500; two other benevolent institutions, same place, \$250 each. —Flushing Hospital, Flushing, L. I., has been voted \$10,000 by the Board of Estimate and Apportionment, provided, however, that the amount be earned by the institution before it can be received. The Hospital will receive \$1 a day for all surgical patients and 70 cents a day for all medical patients. —Fire destroyed the hospital of the Wisconsin Veterans' Home, Waupaca, Wis., November 9. Loss \$15,000; insured for \$10,000. —The formal opening of the new Samaritan Hospital, Troy, N. Y., occurred October 22.

Societies.

The following recent meetings are noted:
Connecticut.—New Britain Medical Society, November 3.
Illinois.—Chicago Medical Society, November 9; Chicago Medical Examiners' Association and Chicago Medical Society—joint session—November 16; McLean County Medical Society, Bloomington, November 3.
Maryland.—Washington County Medical Society, Hagerstown, November 9.
Michigan.—Barry and Eaton County Medical Association, Hastings, October 27.
Missouri.—St. Louis Medical Society of Missouri, November 12.
New York.—Canandaigua Society of Physicians, Ontario, November 3.
Ohio.—Crawford County Medical Society, Bucyrus, November 4; Union District Medical Society, Hamilton, October 27.
Pennsylvania.—Lancaster County Medical Society, Lancaster, November 2; Luzerne County Medical Society, Wilkesbarre, November 2; York County Medical Society, York City, November 3.
Texas.—Corsicana District Medical Association, Corsicana, October 31.
Wisconsin.—Rock County Medical Society, Janesville, November 4.

THE PUBLIC SERVICE.

Movements of Army Medical Officers.—To Santiago, Cuba, Majors Wm. Dolz and Wm. Stephenson, brigade surgeons, to report to the Commanding General, and Acting Asst.-Surgeon Wm. C. Warmley from Washington, D.C., via New York City. To Havana: Major Ezequiel de la Calle, brigade surgeon, as sanitary inspector, from duty with the Seventh Army Corps. To Ponce, Porto Rico: Capt. Geo. M. Wells, assistant-surgeon, U. S. A., for duty in the General Hospital. To Manila, P. I.: Lieut. Irving W. Rand, assistant-surgeon, U. S. A., from post duty at Fort DuChesne, Utah.

To Camps in the South—To the First Army Corps: Major Oscar C. Seure, brigade surgeon, from the Sternberg Hospital to report to the Commanding General; Major James D. Glennan, brigade surgeon, to Lexington, Ky., to the First Brigade, Second Division. To the Second Army Corps: To Camp Meade, Pa., Acting Asst.-Surgeon John S. Schaub,

from Leechburg, Pa. To Camp at Augusta, Ga., Acting Asst.-Surgeon B. C. Leonardi, from Fort Huachuca, Arizona, and Major Lewis Balch, brigade surgeon, to the Second Brigade, Second Division. To the Fourth Army Corps: Majors Wm. J. Kernachan and Wm. B. Winn, brigade surgeons, to report to the Commanding General at Huntsville, Ala.; Major John L. Macumber, brigade surgeon, to the First Brigade, First Division, and Acting Asst.-Surgeon Rafael Echeverria to duty with the Eighth Cavalry. To the Seventh Army Corps: Major Geo. R. Fowler, chief surgeon Vols., relieved from duty with the Second Division, to report to the Commanding General; Major Paul Clendenin, brigade surgeon, assigned as Chief Surgeon Second Division; Capt. W. F. Lewis, assistant-surgeon, U. S. A., to the Cavalry Brigade; Major Samuel T. Armstrong, brigade surgeon, to report to the Commanding General at Savannah, Ga., and Acting Asst.-Surgeon Frank E. Artaud to Savannah, Ga., to the Fifteenth U. S. Infantry.

To post duty: Capt. Chas. F. Kieffer, assistant-surgeon, U. S. A., to Fort Meade, S. D.; Lieut. Basil H. Dutcher, assistant-surgeon, U. S. A., to Fort DuChesne, Utah, and Acting Asst.-Surgeon Francis A. Holliday to Willets' Point, N. Y., from Huntsville, Ala.

To General Hospitals, etc.: To the Josiah Simpson Hospital, Fort Monroe, Va., Acting Asst.-Surgeon Charles F. Craig from the Sternberg Hospital, Ga., to the General Hospital, Fort Thomas, Ky.; Acting Asst.-Surgeon James L. Bevans. To the General Hospital, Fort Myer, Va.: Capt. Wm. F. Lippitt, Jr., assistant-surgeon, U. S. A. To the charge of sick soldiers in Washington, D.C., hospitals: Major John W. Bayne, brigade surgeon.

Sick leave granted: Lieut. B. K. Ashford, assistant-surgeon, U. S. A., and acting asst.-surgeons Henry R. Carter, Jr., John Horn, Ray A. Wilson, Isaac W. Brewer and Wm. E. West.

Honorably discharged—the following Majors and brigade surgeons: Arthur Snowden, John W. Bayne, James M. Jenne and Joseph K. Weaver; Major Jefferson D. Griffith, chief surgeon, Vols., and the following officers of the regular Army (their volunteer commissions only): Lieutenant-Colonels John Van R. Hoff and Valery Harvard, chief surgeons; Majors Adrian S. Polhemus, Charles B. Ewing, R. W. Johnson, Paul Shillock, Ogden Rafferty, Chas. T. Newkirk and Walter D. McCaw, brigade surgeons, Vols.

Resigned: Major Frank Boyd, Surgeon Third Ky. Infantry; Lieut. H. M. Smith, assistant-surgeon First Territorial Vol. Inf.; Lieut. D. S. Humphreys, assistant-surgeon Third Miss. Inf. and Lieut. Otway W. Rush, assistant-surgeon, U. S. A.

Annulment of contract: Acting Asst.-Surgeons Frank T. Disbrow and George G. Morris ordered home from Porto Rico.

CHANGE OF ADDRESS.

Bell, S. D., from Phoenix to Fort Apache Indian Agency, White River, Ariz.
 Borst, H., from Chicago, Ill., to Oelwein, Iowa.
 Baem, E. D., from Kansas City, Kan., to 1117 Holmes St., Kansas City, Mo.
 Birkofer, W. J., from Dickens to Bridge, Iowa.
 Campbell, T. F., from Blunt, S. Dak., to Benkelman, Neb.
 Dickinson, I. W., from Keswick to Boone, Iowa.
 Dwire, D., from Burbank to Wilmington, Cal.
 Fowler, W. S., from Chicago, Ill., to Nordhoff, Cal.
 Fitzpatrick, G. W., from Temple Building to 409 Garfield Ave., Kansas City, Mo.
 Gamble, W. E., from Blue Island Ave. and Harrison to 400 Reliance Bldg., Chicago, Ill.
 Huecker, J., from Denver, Colo., to Waupun, Iowa.
 Holleman, P. W., from Roseland, Ill., to 255 E. 111th, Pullman, Ill.
 Moe, A. J., from La Crosse to Chasburg, Wis.
 McMurchie, from 116 Lysander to Emergency Hospital, Detroit, Mich.
 McCurry, J. L., from Hartwell to Toccoa, Ga.
 Nichols, C. L., from Omaha, Neb., to 35th and Wabash, Chicago, Ill.
 Pinto, A. S., from Panama Park, Fla., to Savannah, Ga.
 Parker, D. L., from 835 to 397 Jefferson Ave., Detroit, Mich.
 Stockton, S., from 413 N. Delaware to Insane Hospital, Indianapolis.
 Soule, C. E., from Chicago to Sheridan, Ill.
 Stover, E. E., from Essex to Lacelle, Iowa.
 Thomas, F. W., from Marion, Ohio, to Pueblo, Cal.

The Journal of the American Medical Association

VOL. XXXI.

CHICAGO, ILLINOIS, NOVEMBER 26, 1898.

No. 22.

ADDRESS.

INTRODUCTORY TO THE ANNUAL COURSE OF INSTRUCTION.

Delivered before the Woman's Medical School, Northwestern University,
Oct. 5, 1898.

BY I. N. DANFORTH, A.M., M.D.

DEAN OF THE SCHOOL, AND PROFESSOR OF THE PRACTICE OF MEDICINE AND
OF CLINICAL MEDICINE,
CHICAGO.

A custom which has the force of an unwritten law has ordained that a course of instruction in a medical school shall be opened by a more or less formal address to be given by some member of the Faculty or by some one who shall be designated by the Faculty. This year the choice has fallen upon me, and I therefore take my place on the program in obedience to the dictates of my colleagues. While my remarks will be specifically directed to the class, they ought to have quite as much interest for our guests who have honored us with their presence this evening, since whatever interests our profession concerns our friends of the laity to an equal degree.

It is now almost fifty years since a woman first forced her way into the medical profession, against the judgment of the great majority of the laity of both sexes, and in spite of the opposition of an overwhelming majority of medical men. One can not read the simple story of Elizabeth Blackwell, narrating her early experiences as medical student and physician without being profoundly impressed with the fact that she paid very dearly for her triumphs and her honors. Yet she *did triumph* and she *did* achieve undying honor; but more than that, she *did* open to her successors—to you, students of the present class—the doors to professional preferment so wide that they will never be closed again.

But, notwithstanding the fact that woman has been fifty years in medicine, her position is not yet quite assured; her claims to professional equality with men are not yet quite admitted; her place in the ranks of citizenship not yet quite settled; and, in fact, the woman physician is still by many people—otherwise sensible and self-poised—regarded as a kind of curiosity or freak of nature.

I therefore ask your attention for a short time, to a consideration of a few of these questions.

1. How shall the woman physician establish her claim to professional equality with men? I answer: First, by simply being a *physician*. If woman is to practice medicine at all, she must practice *all* medicine; she must be an "*all-round*" physician; she must be the family physician, subject to calls from all members of the family—the father, the mother and the children; she must treat all diseases in all sorts of persons, at all times and seasons, without regard to age, sex or social position. In this way—and in this way *only*—can she establish and maintain her equality

with man as a physician. The very moment the woman physician attempts to draw the line and treat only women, or only children, or only certain diseases, she abandons her claims to equality. She erects a barrier as high as the Chinese wall, which separates her from association with physicians on terms of equality. I have very many times heard the criticism from medical men that women were only "*half*" physicians, because they only practice in a limited way. All this must be changed if the woman physician aims at professional equality; she should be satisfied with nothing less. Just as soon as the woman physician voluntarily limits the sphere of her practice, and thus admits, in an undeniable manner, her inability to maintain her parity with men, just as soon will she begin to lag behind in the race for professional distinction. And then will begin the process of professional degeneration in women, which can only end in her ultimate professional extinction.

I answer, in the second place, that women must show their capability for original investigation in the various departments of medicine, and especially in laboratory work; must, in fact, demonstrate that they are capable of doing quite as good work as men, if they expect to reach the scientific altitude which men occupy. I have always maintained that women ought to do better research work than men, because they are endowed with capabilities for such work of the very highest order. More than that, I believe that there are women in the classes before me, who can hardly excuse themselves if they do not do original scientific work which shall redound to the honor of themselves and of their alma mater. I have more than once urged upon the ladies of our classes the necessity for a "*forward movement*" in this matter of patient, painstaking, toilsome, and especially thoughtful, original research work; in fact, upon one or two occasions I fear I have pressed my views with almost unwelcome emphasis. But I feel that my long service in the cause of medical education for women gives me the right to some positive convictions; and it is my positive conviction that we hardworking medical men have the right to expect more efficient help from medical women in the solution of the dark problems in pathology and bacteriology yet unsolved than we have yet had; and that this very graduating class before me ought to enrich the field of pathology by the addition of some facts now hidden in the dark portals of the future. It is by such work as I now indicate, ladies, that you shall gain admission to the profession as the peers and equals of Sternberg and Klein and Ziegler, and other princes who now occupy the field to which you should aspire. Some women have achieved such distinction: we need not go far from home to find at least one; but we should have more, and this Woman's Medical School hungers for daughters who will honor her by painstaking original research, with test-tube and microscope.

2. What position shall the woman physician occupy as a citizen, or in her relations to the body politic. To this I answer, without a particle of hesitation, that the woman physician should be a large-brained, large-hearted citizen, with a definite and positive work to do—a work which she may not delegate or neglect without incurring serious personal blame. And just here I wish to say—in parenthesis—that physicians of the sterner sex are too often recreant to their duties in this respect. When a hard and a close battle is to be fought against any current evil, the leaders are hardly ever physicians, and it is frequently hard work to get them to lift their voices or use their pens, or even go to the polls when a great moral or political question is at issue. I always have had a measure of contempt for Nélaton, who declined to serve in the French Assembly because it would damage his professional dignity; but who does not honor the great Virchow all the more because of his long and eminent services in the German House of Deputies as a statesman and lawmaker? Away with the nonsense that because a man is a physician he must therefore be a cloistered monk, unfit for political responsibilities or duties. But what relation shall the woman physician sustain to community, to society, to her neighbors? She can not vote—not yet. The time may come; *will* come, I believe, when women can vote on all political and economic questions. Personally, I do not care a farthing whether women vote or not. I certainly have no objection to their voting, and if the responsibility of deciding the question were left to me, I should confer the ballot upon women and, then, with profound interest, I should watch the result. But a woman physician should not sit and do nothing because she can not vote. There is plenty of work for her to do—plenty of opportunities for practical usefulness.

She can be a practical teacher of sanitary science in the community where she lives, and this is a sadly-needed work. Every physician ought to be an educator—a teacher—from whom should radiate knowledge which the laity need, which they will gladly receive and which they can not get elsewhere. But the woman physician has special facilities for teaching mothers and nurses the essentials of sanitary science as applied to the home, and therefore she has a special responsibility in that direction. How frequently it happens in practical life, that a few words spoken to a mother may save her child from sickness—perhaps death. How easily the woman physician, with her woman's tact and sympathy, can reach the ear of a nurse or mother, when a male physician who tried to do the same thing would only incur the charge of impertinence or meddlesomeness. And so in other matters, the woman physician can, if she will, exercise an educating, elevating, indeed an almost evangelizing influence in the homes of her *clientèle*. In matters of dress, diet, ventilation, exercise—in all things which relate to healthy homes, healthy mothers and healthy children—the woman skilled in medical science can exert an influence for good for which she must be held responsible in the final reckoning. And as her opportunities are greater than those of the male physician, so is her responsibility greater. A woman can enter where we can not; a woman can utter what we can not; a woman can do what we can not; therefore, she can exercise an influence and accomplish much that we can not.

Remember this, young ladies when you begin your lifework; and remember also that when you are

teaching the people the essentials of practical sanitary science, you are likewise preventing disease, which is an infinitely higher function than curing disease. We are no idle dreamers when we say that, when all the people become practical sanitarians disease will be robbed of half its terrors; and we must add in the same breath that the principles of sanitation must be taught to the people nine times out of ten by their medical advisers. And you—lady students whom I now address—must have a hand in this most beneficial work.

Again: Many of you will be so situated that you can take a practical and active interest in the common schools of your neighborhood. The chief glory of our Republic is the common school. Indeed, so long as the common school—the “district” school, the “little red schoolhouse”—is open to the children of our majestic country, liberty is safe, the people can never be enslaved, and government “by the people, for the people, and of the people” can never cease. But the citizen has duties toward the common school, and the woman physician is a citizen, and that means you. What can you do for the common schools? First, you can take a loving and living interest in it, and thus, by the force of your example, you can arouse interest in others. You can visit the common school, seek the acquaintance of the teacher, if the teacher is a woman, and help her in her work. Some of you have been teachers; you can help some youthful and inexperienced teacher over the rough places that beset her way and thus lend a helping hand to one who is in real perplexity. If you are a good politician, you can get elected as a member of the school board and thus enable yourself to speak and act with authority. The first and only political office for which I was ever a candidate, was Superintendent of Schools in a little New England village. As party lines were strictly drawn, and my party was in the minority, I was promptly defeated, and grievously disappointed, because, among other reasons, I was in rather acute need of the salary, which was \$25 a year. I hope that you will have better success. I hope you will become winning candidates for positions on school boards, with salaries as munificent as the one I missed, and opportunities for usefulness infinitely greater than the one to which I aspired in vain. There is no higher or more imperative duty devolving upon the citizen than the care of the common school, and there is no edifice so important as the schoolhouse, no spot of ground more sacred or more hallowed than the dry and verdureless patch, on which the children of the common school expend their pent-up vitality. You should make this priceless institution your care. You can lecture on hygiene; you can instruct the children, and through them their parents, concerning the laws of health; you can exercise a mighty influence in the improvement of the school buildings, in improving methods of teaching; and in many ways which I can not suggest, but which you can see, as the occasion arises, you can exercise the influence with which you are endowed by reason of your position and education for the improvement and elevation of the common school.

In that beautiful old story, “Locke Amsden or the School Master”—which I read so many times in my boyhood—there occurs an incident which illustrates the precept that I am trying to impress upon you. The “district school” in the little Vermont town, commenced its winter's work under an enthusi-

astic sophomore, and in a bran' new schoolhouse. The frigid weather came, the old "box stove" in the center of the schoolroom buzzed cheerfully as it got hotter and hotter day after day, the new windows fitted so tightly that they could not be opened, and the air became foul from accumulation of "carbonic dioxid"; but the sophomore communicated his own enthusiasm to the scholars, and for a time all things went swimmingly, and everybody was delighted. But by and by a strange langour began to creep over the school; the children sickened and dragged themselves about, listless and forlorn; one of them broke forth in his sleep and repeated the whole multiplication table without dropping a stitch, while another arose from his bed, solved a problem in arithmetic which he could not solve when awake, and went back to bed utterly unconscious of his exploit until he awakened next morning. Meantime the schoolmaster had several times broken forth in school hours, and recited Latin quotations which were all "Greek" to the scholars—and probably to the teacher—and passages from Shakespeare, with wild and frantic gestures, and various facial contortions, in truly sophomoric style; indeed, on one occasion, when an uncommon apathy had stolen over the scholars, he wildly shouted that his name was "Norval," and that his father fed his flocks "on yon Grampian hills," when every scholar knew his name was Jeremiah Jenkins, and that the "hills" were only the Green mountains; and hence it began to be darkly whispered that the schoolmaster had formed a league with the evil one, and was practising the "black art" and "bewitching" the children. So on a cold dreary winter's night, a school meeting was called in the schoolhouse for the purpose of "investigating" the schoolmaster, and ridding the excited community of his baleful presence; but while the people were solemnly discussing the awful situation in the close and heated room, the village doctor came in, sniffed the tainted air, and calmly informed the anxious group of citizens that ventilation was the cure needed for the form of witchcraft which they were fighting, and after the carpenter had lowered the upper window sash, and thus allowed the evil air to escape, the people sheepishly went home in a happier frame of mind—and the bright young sophomore became, of course, an apostle of sanitary science. It is useless to add that he married the beautiful daughter of the richest man in town, that he went to Congress, and after a glorious and useful career, was gathered to his fathers. Whether the story is true, or not, its lessons are true so far as they relate to the schoolhouse and its occupants, and the timely service of the village doctor, who did not confine his practice merely to administering Dover's powder and boneset tea to the sick, but who stepped out into a larger sphere, and became the guardian of the health and lives of the children of the common school. Similar opportunities will come to you; not that you will encounter such superstitions as lead to belief in witchcraft and the "black art," but you will find plenty of schoolrooms, churches, halls, and even houses, where you can confer a real blessing by pointing out the necessity for fresh air and ventilation. May I hope that you will improve the opportunities as they arise, and thus prove yourselves good citizens, as well as good physicians.

I have pointed out a few of the duties which will legitimately devolve upon you, both in your relation to the profession and to society or the body politic.

Other duties or other opportunities for usefulness will arise as you accumulate experience and acquire influence. I fully believe that you will make the most of your opportunities, and as a necessary corollary, that you will make the most of your lives.

Let me in conclusion glance for a moment at the past, and then for a moment at the future. In an earlier part of this address I have said that about fifty years have elapsed since a woman made her entrance into the medical profession in this country. At first glance one is inclined to think these fifty years have been rather barren of results; that too few women have reached professional eminence and made themselves felt in the medical world. It is indeed true that the number of women who have distinguished themselves, either in practical or theoretic medicine; either in the hospital ward, the lecture-room or the laboratory, is small in comparison with the number who have graduated. Nay, I will go a step further, and say that the ratio of distinguished medical women is smaller than the ratio of distinguished medical men, in comparison with the number of graduates. Let us inquire briefly into the reason for this. I do not think we will have far to seek.

In the first place, twenty-five of these fifty years were spent in battering down the walls of opposition and prejudice on the part of both physicians and laity, which barred the way of the woman aspirant for medical honors. Twenty-five years ago the woman who announced herself as a medical student had to encounter opposition, ridicule and not infrequently absolute insult, as she made her weary way toward a medical degree, which brought her few privileges and less honors. She was not welcomed in the lecture-room, in the clinical amphitheater or the hospital ward. It was not uncommon for the clinical professors to indulge in remarks which would bring the blush of shame to the cheeks of the lady students, and arouse indignation on the part of male students who were gentlemen as well. It would be impossible for a woman to do her best work under such dispiriting circumstances, and it is no wonder that but few reached the goal of their ambition. But again, at the time of which I am speaking, after the female student graduated, she generally met with a very frigid welcome on the part of the profession, and hence she was alone in her glory. She lacked that inspiration which a community of effort engenders; it is impossible for one to permanently keep the fires of enthusiasm alive in complete isolation. Interchange of thought, interchange of counsel, comparison of efforts and comparison of results are necessary for the professional mind of woman as well as man; but these all-important aids were frequently denied to the woman physician.

Pardon me, ladies, if I mention one other fact which militates against the greatest success of women. It is the fact that a majority of young medical women do not settle down to months and even years of hard, and often unrequited, labor, as the indispensable prerequisite of success. There is no other road to success. You must work incessantly—pay or no pay. You must work in your libraries, in dispensary service, among the poor, anywhere, everywhere, night or day, so that you acquire experience, dexterity and knowledge. Young medical women often shrink from the trying ordeal that awaits every young physician who seeks success in a large city, where competition is hot, and every desirable position is fought for

by a hundred applicants. And especially is this true, if our young graduate happens to be in a condition of financial anemia, as is too often the case. Alonzo Clark—the greatest physician New York has ever produced—a man who stood as the acknowledged head of the profession in the field of pathology and practice, whose consultation practice became so enormous that at last he had to refuse as many calls as he answered, spent his early years in dire poverty, haunting the hospitals, clinics and morgues of New York like a spectre—frequently lacking the means to buy a dinner—but always at work—at work—at work. “Go thou and do likewise;” go hungry if you must; dress plainly if you must; endure neglect from society if you must; but study, observe, experiment, think, write—work hard and constantly, and success is sure to come. I know; I have been through the same hard school myself, and so have some of my colleagues now here present.

The position of woman in medicine is assured. She has come to stay. The past fifty years have been years of pioneer work; all honor to the noble women who have cleared away the obstacles and opened up a great highway for you. Their work was necessary; see to it that you appreciate it at its just value, and render unto them the honor that is their due.

Meantime a new woman is being slowly evolved. For twenty-one years I have watched the evolution of the medical woman myself. Fifty years more, or three generations from Elizabeth Blackwell, will be required to complete the work. The medical woman,—the woman with the scientific cast of mind,—the hard-working, patient, self-denying, plodding student is almost here. Her representative, her *avant courier*, is here—is in this very class, in the plural number—an earnest, a promise, a prophecy of the host yet to follow. I shall not see the fruition of the promise; but, as I look back on my career as a medical teacher, now drawing to its close, I glory chiefly in the fact that I have had something to do in the work of opening the doors of medical advancement to American women.

CHILDREN'S DISEASES.

Presented to the Section on State Medicine at the Forty-ninth Annual Meeting of the American Medical Association, held at Denver, Colo., June 7-10, 1898.

BY CHAS. H. SHEPARD, M.D.

BROOKLYN, N. Y.

Our purpose in this paper is to enforce the efficacy of heat in the treatment of the ills of infancy and childhood, as well as to illustrate the pleasing and peculiar adaptability of the Turkish bath, which is the most perfect form of using heat in all cases of disease. What we have to say is based on experience in raising a large family, as well as some considerable practice with patients during a period of thirty-five years.

While a vast amount of disease and suffering that occur in early life is produced by errors in diet, clothing and exercise, a large portion of it comes from want of cleanliness, added to by impure air, unwholesome dwellings, etc. Lack of knowledge is responsible for many pernicious practices that lead to debility, and too frequently an untimely end. Impure air, of

whatever nature, has the most deleterious influence upon infantile life, producing a startling mortality in all our large cities, and a want of cleanliness is equally well known to be many times more injurious. Never was the old adage: “Heat is Life and Cold is Death,” more true than in the treatment of children's diseases. The simplest and most desirable form of heat is that derived from the one indispensable source of all heat—sunshine. We well know that all vigor comes from the sun, both to the animal and vegetable world, that it vitalizes the nervous system, develops the red discs of the blood, and also that it is the most powerful foe to contagion. The International College of Physicians which lately met in Italy declared sunlight to be the most practical of all antiseptics. A sun bath is the only remedy needed in some cases. Like the action of the sun's rays—gentle, yet all-powerful in quickening life—so does heat, in its proper administration, renew and vivify every function of the body, while at the same time it is so simple and available that none need suffer for the want of it.

Whenever cleanliness with infants is neglected, disgusting, painful and obstinate cutaneous eruptions are likely to occur, or the foundation may be laid for derangement of function, or serious disease of some internal organ. At no period of life is injury more liable to be produced, for at such time the vital resistance is at a low ebb, therefore repeated ablutions of the surface are most important. Again, the skin and the mucous membrane of the digestive canal and of the respiratory organs in an infant, are the principal surfaces upon which morbid impressions are received, consequently they are those in which disease usually first shows itself and the exhalent function of the skin is extremely active, while calorification is feeble. We are also to recollect that very frequently the cerebral symptoms which occur during infancy and childhood are altogether independent of disease of the brain or spinal marrow, being due solely to functional disturbance of the nervous centers, the result of reflex irritation. At this period, when the functions of life are confined to nutrition and development, it is important that we obtain the most favorable conditions for children; not alone to promote their normal growth and activity, but also to prevent any predisposition to particular forms of morbid action, as well as to give strength to overcome whatever prevailing disorder to which they may at times be exposed, whether it may be sympathetic irritation or the ordinary crises through which they usually pass.

In the treatment of children, much more than with the adult, is the cheerful and what may be called the hypnotic influence to be exhibited. Many times the dread of a disease is worse than the disease itself. A cheerful and relying faith in the efficacy of the treatment to be administered is of the greatest value. When the ablest physicians confess to a feeling of helplessness, it is time to give Nature an opportunity to recover herself, and instead of initiating measures that make a draft upon the vital powers, the part of wisdom is to remove, in the gentlest manner possible, all obstructions to the harmonious working of the functions, and encourage every effort the system is making to throw off morbid conditions.

Most of us believe that the death of young children is not a necessary or inevitable result of any disease from which they are suffering, but rather that it is an accident that may often be foreseen by any one who will cultivate the habit of minute observation. Many

an infant life has been saved or sacrificed by the observance or the neglect of things which are too apt to be lost sight of as utterly beneath the dignity of science. When we stop to consider how much benefit is to be derived from the simple use of heat, whether it be the internal use of hot water or the external use of hot compresses, or the primitive forms of a hot bath, it may reasonably be supposed that the scientific application of heat in the form of hot air, familiarly known as the Turkish bath, would be productive of a more uniform and certain result, and this has proved to be the case, to the surprise and delight of many an anxious parent.

To illustrate the action of the Turkish bath in infantile diseases, the following cases are related:

A male child, about six weeks old, was so nearly starved by the ignorant management of his nurse, that a complete case of marasmus was developed. The most important part of the child's treatment, after inaugurating a new régime, was a daily Turkish bath, supplemented by a gentle oil rubbing, which was continued for the succeeding twelve months. He was taken into the hot room and placed on his back, on a bench covered with several thicknesses of blanket, there he would lie and play with his toes and sweat freely, then he would be taken to the shampooing room and gently rubbed with soap and warm water, then a delicate spray of warm water would wash him off, after which he would be wrapped in a sheet and blanket and invariably drop off to sleep. All these processes gave him delight, and his improvement dated almost from the commencement of this course. He is now over 21 years of age, and an active member of the National Guard.

Another case was that of a boy 3½ years old, who was taken late at night with the harsh ringing cough of croup, together with labored breathing. He was carried to the hot room of the Turkish bath. At first the heat did not seem to give relief; on the contrary, the symptoms were apparently aggravated. Hand-rubbing of the arms and legs was then begun, which was pleasant to the child. An expression of enjoyment, which was his first spoken word, encouraged perseverance. Very soon perspiration began, and then the unpleasant symptoms gradually vanished. He was kept in the hot room about an hour, until his breathing was perfectly normal and the perspiration most abundant, when he was washed off and put back to bed. He went directly to sleep, had no more coughing, nor was he heard from again until after daylight the next morning. That was the last of the croup.

Another case was that of a male child stricken with infantile paralysis, as a sequela from an attack of eruptive fever. Both the lower limbs seemed deprived of the power of motion. The entire treatment consisted of a daily Turkish bath, followed by oil rubbing, and the result was that in a few weeks his activity was regained and his restoration was complete. Today he is a stalwart man, over six feet in height.

The internal administration of hot water and the use of the Turkish bath in diarrhea and even dysentery, has proved most salutary, both with children and adults. The use of hot water in the hands of Dr. Elmer Lee, during the last cholera plague in Hamburg, was crowned with the best results. The first stage of cholera is at once arrested by a Turkish bath. Children liable to colds and catarrhal processes in general are rendered less susceptible by the bath, and it is also a valuable tonic to the vascular and nervous system, from the agreeable impression made on the peripheral nerves. In all fevers and inflammations the Turkish bath has proved a highly important therapeutic measure. Its antipyretic effect is enhanced by the rapidity with which morbid material is eliminated from the body, and thus the cause of the fever is removed. This also includes such cases as those of erysipelas, measles, scarlet fever, together with pneumonia and malaria.

The Turkish bath has produced the most happy results in all cases of rheumatism in children, whether from hereditary predisposition, which is well known to have a remarkable influence, or as a resultant of

septic poisoning from other disease, such as scarlatina. While rheumatism may be developed from a chill, yet it would not appear except from a lowered tone of the system, produced by exhaustion from some excess. Even excess of food may bring about such a result. The most reasonable theory in regard to the method in which chill acts in producing rheumatism is that the chill disturbs the nervous system, and nutrition is disturbed thereby, and that the lactic acid, or some other acid of an irritant character, is retained and acts as a poison, which produces the phenomena of acute rheumatism. While chronic rheumatism is rare in children, it is acknowledged by many of the best authorities that the means productive of the most good are hot baths.

Rheumatism in children is often followed by a large class of ailments, some of which result in veritable heart disease. All of these may be avoided or aborted by an early resort to the use of the hot air baths. Instead of being followed by an embarrassed and weakened heart, the purification of the blood renders the circulation perfect and the heart's action stronger.

Many of the drugs advocated for the treatment of rheumatism have been found useless, and some harmful and even dangerous. The fact that they are heart depressants of dangerous power negatives their use, especially with children. The use of anodynes can not be too strongly deprecated. Their action is simply to benumb or deaden nerve action, whereas the patient, at such times more than ever, needs the full integrity of the entire nervous system. Then it is that nature seems to loathe everything in the way of alimentation, plainly indicating that the digestive apparatus is in no condition for the work of appropriation. If the food is not relished or retained, it should be taken as a loud and natural protest against its being forced upon the patient. To force food then is like adding insult to injury. A copious use of hot water at such times gives wonderful relief in mitigating pain and aids materially in washing out poison from the system.

Heat, in the treatment of the diseases of infancy and childhood, is an agent so universally applicable and so readily at hand, from the tenement to the villa, that it deserves to be placed at the head of the physician's armamentarium. Among the readiest means of applying heat, where the Turkish bath is not available, is the hot compress, a simple device composed of four or more thicknesses of flannel wrung out of water as hot as can be borne. This may be placed next the body, covered by a dry one of the same material and thickness, but made a little larger—the size to depend upon the object to be attained and the age of the patient to be operated upon. One large enough to cover the entire front of the body, from the neck to the pubis, has been known to bring about a profound change in many a little sufferer, who could not tell what was the matter with him, and it has to all appearances saved the lives of many who were suffering from scarlet fever and other eruptive diseases. Cold water will dissolve most substances, but its power is greatly increased by using it at the temperature of the body, and it will dissolve most waste material that may collect in the intestinal tract and remove it by the various methods which the body possesses for getting rid of waste products. The waste substances, if not actually poisonous, are at least mechanically injurious to the body. They can either be got rid of, or allowed to get fixed in the

body, with resulting pains and headache. A sufficient supply of boiled water, drunk at the body's temperature, will remove many a source of danger. The internal use of hot water is invaluable to the infant suffering with colic, as well as to the adult suffering with sick headache. Another convenient and ever-ready form of applying heat to suffering children is by means of a hot sitz-bath, for which a common washtub may be utilized, providing that the water is as near 110 degrees as may be. Should the patient be too nervous to be introduced at that heat, it may be made several degrees cooler at first and gradually increased until the desired temperature is attained. To utilize as much of the heat as possible, a sheet should be first placed over the child and tub, followed by one or two blankets, reserving the head for the free access of air and an occasional sip of cold water. When the perspiration begins to show itself freely on the face, a successful result may be predicated. It is well to finish by washing off with cool or cold water, in order to tone up the skin and prevent what is called "taking cold" afterward. This device is capable of being utilized in an infinite variety of conditions, and when in intelligent hands has never been known to do harm, but on the contrary has brought about beneficial results in thousands of cases. With the addition of a foot-bath of the same temperature this same arrangement has produced wonderful results in children of much larger growth. W. H. Wooster, of Australia, relates the following:

A little girl about 4 years of age was bitten on the foot by a poisonous black snake. Symptoms of poisoning quickly followed, such as swelling, coldness and stiffness, the lips as thick as one's thumb, and the hollows on each side of the nose filled up level, and of a steel-blue and sea-green color. The arms, lower limbs and body were becoming blotched with irregular raised parts. The pulse became exceedingly feeble. I hesitated, as no physician was nearer than eight miles, but concluded to try the "hydropathic sweating pack," to produce perspiration. The child was placed in a tub of hot water, and blankets thrown over her, leaving the head out. This was followed by a hot wet sheet and wrapping in two blankets, closely tucked in. The heart action had almost ceased. In fifteen minutes an improvement was apparent. The dark rings around the eyes became less marked, the blue green tints less ghastly. She became conscious. In an hour she was taken out of the pack. The swelling, blotches, stiffness, had disappeared, and the patient was washed off with cold water, rubbed, and next morning she was at the breakfast table.

What is called a corn sweat has been utilized in some sections of the country. This consists of a number of ears of freshly boiled green corn, with the husks on, wrapped in cloths and placed around the body of the invalid and then the patient covered with blankets. The heat and steam from the hot corn soon brings on a profuse sweat and has relieved many cases of congestion. To give a lime sweat, take a piece of quicklime half the size of the fist and rub it over a bed-sheet well dampened, but not so wet that water will drip from it; wrap this sheet in a dry one and fold it several doubles; place two bundles prepared in this way, one on each side of the patient, in his bed; an abundant steam will come from the damp sheets and the lime, which will keep warm for over an hour; by that time the lime is reduced to a powder and can easily be removed from the sheets without injuring them. In using this method it is not necessary to give the patient warm drinks, nor to overload the bed with blankets. A balsam sweat can be given by placing a few branches of balsam in a pail of hot water and then placing in the water one or two hot flat irons—hot stones would answer the pur-

pose—to create a plentiful supply of hot steam. This is to be placed under a chair in which the patient is seated and covered with a sheet first, followed by two or more blankets to retain the heat and moisture. Twenty minutes of this bath, though sometimes it has been used much longer, has proved most effectual to secure a thorough sweat, and the empyreumatic oil from the balsams contributes to the pleasantness if not the utility of the bath.

Where there is a bathtub in the house a very good sweat can be produced by running into the tub about two inches of water as hot as can be comfortably borne. Let the patient sit in this and lave the hot water over his body, at the same time allowing hotter water to flow into the tub, continuing the process until a profuse perspiration is established, then pull out the plug to allow the hot water to run off and turn on the cold water to wash off the body and secure a good reaction. An alcohol sweat has been successfully used by many mothers. It consists of an alcohol lamp placed under a pan of warm water, with the child seated on a cane-bottomed chair, and then all but the head covered with blankets. This is an effectual manner of breaking up a cold. A sulphur bath consists of a box arrangement wherein the patient can sit with the head out. The attendant burns a sufficient amount of sulphur in the lower and rear part of this box. This produces a profuse sweat in a short time, and has been used with great success in cases of rheumatism. It is a sure cure for the itch. The makers of portable Turkish baths are advertising very freely in the papers, arrangements costing from five dollars up that are capable of doing very effective work and will be found useful in many places.

All the aforementioned are but rude and primitive efforts to accomplish what is so easily, promptly, and thoroughly brought about by that most complete of all baths—the Turkish bath. The great beauty and utility of the use of this bath in the treatment of children's diseases consists in the ability to quickly abort what would otherwise prove a serious disturbance. Many such difficulties begin with what is called a cold, which is otherwise a condition of repletion. The Turkish bath, by its eliminating power, breaks up this condition and quickly relieves the pressure. Resort to the bath in such cases constantly tends to the better growth and development of the child. We know that every period of sickness through which a child passes, interferes with its growth and development, and sometimes leaves deformities in its track. For this reason the Turkish bath is to be considered one of the best friends of childhood. The pleasure with which its processes are enjoyed is a most marked contrast to that of the ordinary treatment. The delightful feeling of being more thoroughly clean than is possible under any other process is most satisfactory and enduring. It is also invaluable in all infectious diseases, as heat destroys the germs, and renders the soil barren, thus producing unfavorable conditions for any disease to progress.

The readiness with which the Turkish bath can be accommodated to the necessities of any case, renders it most admirably adapted for such work. It promotes the natural action of all the functions of the body, bringing to every organ its equal and appropriate nutriment. It thus aids the development of all the functions which may be deficient in activity, and secures a harmonious working of the forces through which physical life is perfected and enjoyed. Thereby

we have a better opportunity to attain the full measure of social, intellectual and spiritual life. Those who desire for their children the greatest physical good—and what parent does not?—should provide for them the privilege of at least one Turkish bath every week. No one thing would tend more to promote their growth and development. All who would hasten on the good time, and honor themselves, can scarce find a better field of work than that of popularizing these baths, for unless all signs fail, they will yet prove one of the greatest blessings to mankind. In order that their complete benefits may be realized, there should be large public Turkish baths established by the people, that would be readily available to every child in the land, as well as to the parents. Every city or town securing for itself this grand privilege, would find itself many times remunerated in lessened taxes for the sustenance of its paupers and criminal classes, better health and a longer term of life for its children, as well as in the general refinement of its people.

81 Columbia Heights.

CONTROL OF DIPHTHERIA.

Presented to the Section on State Medicine at the Forty-ninth Annual Meeting of the American Medical Association, held at Denver, Colo., June 7-10, 1898.

BY W. K. JAKUES, M.D.

CHICAGO.

The knowledge which careful investigation has given the medical world has placed within our hands the means of controlling diphtheria—the most fatal disease of childhood—as it has never been controlled before. Just in proportion as this knowledge is made available when needed, will be the success with which the disease may be held in check. In the past, diphtheria has been in the hands of the family physician, the health official taking little or no part in the treatment, except to warn the public by a placard and insist upon isolation. But our present knowledge of the disease demands a greater participation than heretofore by municipal as well as State officials.

Diphtheria is influenced by every factor that affects the physiologic resistance of the human system. History shows that in every large city, in periods varying from seven to ten years, the disease becomes epidemic, probably due to racial and climatic conditions which cause an increased predisposition, as well as favorable conditions for the virulence and spread of germs. During the summer, or the seasons of least susceptibility, the Klebs-Löffler bacilli are preserved in dark tenement and basement houses, and other favorable places where sunlight can not destroy them. During seasons of increased predisposition, they spread from one susceptible individual to another. The Klebs-Löffler bacilli, inoculated on the mucous membrane, grow with a rapidity proportionate to the susceptibility of the individual. The bacilli, in their growth, produce a ptomain, very destructive in its nature, which causes necrosis at the point of invasion, and a general cell-destruction, corresponding to the degree of virulence and cell-resistance.

The symptoms caused by the invasion of the Klebs-Löffler bacillus are simulated by several other germs, with which it is often associated. When this is the case, the symptoms of the Klebs-Löffler bacillus may be so obscured by those of the associate germs, that its presence can not be discovered in the early stages except by the microscope. Mucus taken from the site of the invasion contains the germs exciting the

inflammation, and they may be clearly identified through the microscope, after a few hours' cultivation, before the production of membrane or other clinical evidence of diphtheria.

Antitoxin is a specific in the early stages of the invasion of the Klebs-Löffler bacilli, and the mortality increases in direct ratio as the diagnosis and administration of the serum are delayed. Then the first necessity in the control of diphtheria is an early bacteriologic diagnosis; the next, the proper use of antitoxin. Here begins the responsibility of the family physician, and upon his conduct rests the subsequent results. He must first appreciate the danger that lurks in a simple sore throat, and realize that bacteriologic as well as clinical evidence is necessary for an accurate diagnosis. Laboratory work of any extended nature is seldom possible for the general practitioner, because of the necessary time and equipment; hence this work should be supplied by those whose interests are most involved, and who are best prepared to do it. These are the officials of the health department, who are the guardians of the public welfare, and whose duty it is to help suppress anything which threatens the health of the body politic. Any contagious disease which manifests itself in the form of an epidemic is directly within the jurisdiction of municipal health officers, not for individual treatment, unless it is clearly beyond the scope of the physician, but for the provision of such measures as will enable the physician to best control the disease.

A remedy is only a remedy when applied to the particular disease it is adapted to cure. Antitoxin is a by-product of the Klebs-Löffler bacilli, and is just what its name implies—a remedy against or opposed to the toxin produced by these bacilli. Having been made possible by the revelations of the microscope, it should be applied as scientifically as it was discovered. Following the first reluctance to use antitoxin at all, has come the tendency among some physicians to administer it indiscriminately in any and all cases of sore throat. This is not as serious in its consequences as the total omission of the remedy, for one is likely, by chance, to cure a case of real diphtheria; but it is unscientific and renders unreliable the record of its results. Given a remedy and its specific action, based upon a certain condition, and the means of discovering that condition, and the physician of today is master of a disease which for centuries has been an unconquered foe of the race.

It may be questioned as to whether or not municipal or State authorities have the right to demand certain treatment of a disease from physicians whom they have licensed to practice, after having been convinced of their ability to do so. But the majority of physicians now practicing received their medical training before the existence of much of the knowledge upon which our present experience is based. It is not pleasant to admit that some doctors who boast an experience of a quarter of a century, or even a decade, are prone to prefer this experience to "new-fangled" theories. Nothing makes a physician feel so helpless as a consultation with an old physician, who declines antitoxin with the remark that he has used iron and sulphur, and similar remedies, for thirty years, and never lost but one or two cases of diphtheria. There is no argument which will convince such a man that some of the cases may not have been diphtheria. He knows it when he sees it, though he

sees it but seldom; and the expert who treats it all the time dares make no such assertion without the confirmation of his microscope. It is this class of physicians who keep up the death-rate in diphtheria, and who make it absolutely necessary that health officers shall demand the use of such methods as have been demonstrated as most efficient in protecting the public and the individual. If the foregoing were not sufficient reason for action on the part of health authorities, there would still remain the fact that diphtheria is a disease of the poor people, and as such, requires protection and aid.

In the individual who is protected against diphtheria, there is a constant amount of antitoxin present. It is one of the products of cell-life, under favorable physiologic environment, and is carried to all parts of the body. When the mucous membrane becomes congested, the functional activity of the cells is arrested and their resistance to the invasion of hostile germs is weakened. The toxin of the invaders acts as a stimulant to the other cells throughout the body, causing an increase in the production of antitoxin. This is carried to the site of the invasion by the blood and so fortifies the surrounding tissues that the invasion is stopped. With this explanation one can understand how the Klebs-Löffler bacilli may be present in the mucus of the mouth for weeks without producing an invasion; but when vital resistance is lowered by cold, hunger, loss of sleep, anxiety, menstrual period, or other debilitating factors, the disease manifests itself.

A high degree of physiologic resistance is the surest safeguard against all disease. This condition is only possible with hygienic surroundings; hence it is obviously the first step toward the suppression of disease, particularly of a contagious nature, to demand of the filthy man that he shall keep himself and his surroundings clean. It is a very fine line which separates the duties of the health official from those of the family physician, and the highest degree of success can only be attained by their harmonious co-operation. Health officials are dependent upon doctors for much statistic information involving time and labor, for which they are not compensated. Not only in return for this, but as a means of guarding the welfare of the public, the authorities should provide such facilities for physicians as will render the treatment of contagious diseases as efficacious as possible.

The expense of a laboratory to a community is small compared with its benefits, and when properly equipped, with an experienced bacteriologist, will prove a very important factor in the hygienic government of a city or town. The culture medium should be properly prepared or the examinations will be confusing and misleading. The change in the forms of the Klebs-Löffler bacillus, and the modifications in cultural developments, owing to associate germs, make the identification of the bacillus sometimes difficult. Diphtheria work in all its phases is greatly facilitated by experience, and all the cultures of a community are no more than sufficient to give a bacteriologist a knowledge of the varying forms.

From a legal standpoint, it may be a serious matter to placard a house or place of business, and it should not be done unless the department fortifies itself with evidence of the contagious nature of the disease. This it can best do by making its own cultures, or by doing the work for physicians.

Antitoxin is a product which should be subjected

as little as possible to the vicissitudes of commercial exchange. It deteriorates with age, and the irregular demand often leaves it on the druggist's shelf for months. When it is needed, it is usually in an emergency, when the life of a patient is depending upon the quality of the first dose of serum. Owing to the large profits accruing from the sale of antitoxin, irresponsible firms have been tempted to place an unreliable grade of the serum on the market. Foreign governments have taken measures to protect their cities by restricting the manufacture of the article. If State officials are not able to do this, they are at least in a position to investigate and satisfy themselves of the best grades on the market to be supplied. No greater service can health officials perform than to arrange for a fresh supply of a reliable grade of antitoxin, throwing careful restrictions about the distribution of that intended for purposes of charity. Delayed treatment means increased infection, and the control of the disease in the tenement districts means fewer funerals on the boulevards.

These facts furnish the basis for the plans now used in cities to reduce the death-rate in diphtheria. The predisposition to this disease is as great in Chicago as in any city of its size in the world. Its geographical situation makes it the commercial center of the United States; while the immense system of railways radiating from and through it, make it a rendezvous for all classes of foreigners, as well as an incalculable means for the distribution of contagion. Added to this are its crowded districts and its raw lake winds, which have together made the city a shining mark for diphtheria. By furnishing convenient culture media, microscopic examinations, the best obtainable grade of antitoxin, and the services of expert physicians as inspectors and operators, Chicago now points with pride to a death-rate which has been reduced from 37.5 to 6.7 per cent.

In the rural districts, where these means of controlling diphtheria do not exist, the mortality is almost as high as ever. If such a reduction can be accomplished in a large city, under circumstances most favorable to the existence of diphtheria, a similar plan ought to be even more effective in country towns where hygienic conditions are most favorable to health. The methods used in Chicago can be applied and carried out, with some modifications, by the health department of any city or town. Where such an office does not exist in country places, the work can be carried on by direction of State officials with very little expense. The equipment for diphtheria work would represent but a small outlay compared to the advantages to be reaped from its protection. There is no disease of childhood which finds an unprepared country doctor quite as helpless as the malignant form of diphtheria. Without bacteriologic facilities, it usually takes several deaths to convince a physician what he has to deal with and provide for. That part of the control of diphtheria to be performed by health officials is largely by direction of effort. Previous preparation is very important and should occupy the summer months, when a physician's work is light, and he can devote time to the acquirement of knowledge concerning the morphology of the Klebs-Löffler bacillus, and the best method of doing the work.

The fear of cholera or an epidemic of yellow fever has caused State officials to spend thousands of dollars in questionable methods for the protection of the

people; but a disease which is absolutely preventable has received little or no attention from these officials. The best authorities on the subject believe that if children were given the highest scientific protection, there need not be a single death from Klebs-Löffler diphtheria. We have the knowledge and the remedy; all we lack are the individuals in official life to apply them for the protection of the public.

4316 Greenwood Ave.

ALCOHOL ON TISSUE AND CELL GROWTH.

WHAT RECENT INVESTIGATIONS SHOW OF ITS DESTRUCTIVE ACTION.

Presented to the Section on State Medicine at the Forty-ninth Annual Meeting of the American Medical Association, held at Denver, Colo., June 7-10, 1898.

BY T. D. CROTHERS, M.D.

SUPERINTENDENT OF WALNUT LODGE HOSPITAL,
HARTFORD, CONN.

I can only hope to point out some general facts which have been confirmed by repeated observations of many persons. Within five years an increasing interest in alcohol has begun in the laboratories, and the question of how alcohol acts on the body is recognized as the great coming theme. The theories of the past are called in question, and a large number of scientific men are trying to solve the problems of alcohol, only to find how complex and difficult they are. Our familiarity with the effects of alcohol are far beyond all knowledge of its chemistry and pathology. We interpret the symptoms and theorize from them without any knowledge of the actual conditions present. A change has come and the question is "Why should alcohol cause exhilaration or stupor, delirium and delusion? Why should profound changes follow its use with intense degeneration and destruction of both body and mind? These questions are to be answered in the future by exact chemic and laboratory research confirmed by clinical observations.

The new physiology of modern research shows that the body is an association of cells. Each cell is a physiologic unit, and consists of a large quantity of minute structural elements which have the form of granules. These are not alike, but assume a number of different forms, differing in regard to irritability also with regard to external stimuli. Under specific stimuli some of them grow and divide, while others remain undisturbed. It is from a predominance of one or other of these sets of cells that the specific character of a cell is determined. The sum total of these granular energies makes the life of the cell. These are the ultimate organic units of life. In all these cells there are specific functions, capable of acting along certain lines. All cells have functions of assimilation, growth and sensibility. All have stimulus and force, both chemic and physical.

The influence of surroundings is the stimulus which calls out certain functions and activities. The perfection of life is the perfect balance of these cells in function and growth. Any substance which interferes with their specific action, changing their direction and movement, which disturbs their assimilation, growth and sensibility; or which breaks up their stimulus, force and chemic and physical relations, is serious and of vital influence to the integrity of the body. Cells may be injured, poisoned, impoverished, and diverted from healthy growth, and be repaired. When the injury passes a certain limit, death takes place and no recovery follows. With

these physiologic facts in mind, we are able to understand how poisons may affect the cells and tissues.

One of the prominent effects from the ingestion of alcohol in the stomach is the increased action of the heart and rapidity of the blood-current. Dr. Berkley has shown that the circulatory apparatus is damaged both by the presence of a poisonous irritant circulating in the blood-current, and the deteriorating action of alcohol on the leucocytes. These bodies are palsied and swept by the blood-stream into the cerebral circulation, and from the atonic condition of the heart muscle and the muscular walls of the arterial system not being able to force them through the capillaries equally with the red-blood corpuscles, by reason of their larger size, they accumulate in the finer capillaries which surround the cells, plugging them up partially with backward pressure on the arteries. These retain the irritant poison, increase the danger to the walls of the capillaries, and add new sources of irritation.

The leucocytes degenerate and disintegrate, and ruptures of the walls of the finer capillaries are frequent. The practical destruction of the leucocytes and driving them in masses in the meshes of the brain, together with the alcohol irritant has two specific influences on the cell: one on its nutrition and the other on its dynamic force. The nerve-cell, as we now understand, is composed of numerous dendrites or filaments, which project out from the cell body, in contiguity but not in contact, with filaments of other cells and nerves. These are altered, retracted and shrunken from the influence of alcohol.

Dr. Berkley, in describing the lessons from the action from alcohol, showing the shrunken cells, says: "One striking fact of the degenerative process is that a number of the cerebral and cerebellar cells remain apparently intact unless the use of alcohol is excessive. About every third or fourth cell shows pronounced alterations. This part does not militate against the conception of the degeneration as a pathologic entity from the standpoint of numerous forms of dementias, and chronic alcoholic psychoses, for the nerve elements of the cerebrum are intricately connected one with the other by means of their conductor endings and the knob-ended gemmule, between which the dynamic forces originating in the cell body, pass from one cell to the other over the almost imperceptible space that is present between the two; and thus the death of a single cell may destroy the normal relations between dozens of other cells, and in this way induce an inco-ordination of thought and action, while the majority of cellular elements retain their histologic normal characteristics."

Dr. Andriesen found that alcohol acted on the cell body, causing changes of the granules, eroding them, as it were, breaking up the normal distribution, and causing them to gather in masses like ruins. In some cases changes would start from several points in the cell body and be followed with local excavations and breaking down into little débris. The external changes of the form would be shrunken and depressed like a battered hat. The dendrites and fibrils would be shrunken and wrinkled, with small irregular swellings. These changes begin in the nutrition of the cell and its dynamic activity. Alcohol breaks up nutrition and its power of generating force or regularity, when generated. In fatigue, the form of the nerve-cell is changed, and its filaments re-

tracted, so from alcohol the same condition in a pronounced degree follows. Dr. Andriesen shows that the functional activity of the nerve-cell is suddenly increased by the action of alcohol, and its nutrition equally depressed; that both the dynamic and nutritive powers are degraded, broken up and paralyzed. The sudden absorption of the water of the cell and the intrusion of the alcohol toxins, cutting off nutrition and diverting the dynamic force, are depressant and degenerative. The result is most clearly seen in the symptoms which follow, which are so uniform as to be almost the same in all cases. These may be stated thus: diminished power of resolution, of concentration of muscular and mental energy; lowering of the moral and ethical sense; failure to get rest from sleep; nutritive derangements, and finally mental disturbances with emotional changes, delusions, sensorial failures, and so on into inanities, at first slight, then profound and grave.

The fact is well attested that alcohol even in small quantities affects protoplasm, diminishing the vital phenomena therein; this, in addition to the palsy and cessation of movement of the leucocytes in the blood, taking away the resisting power to disease, and imperfect oxygenation with consequent retention of waste material, are groups of facts well established. Prout, Smith, Harley and others, proved conclusively that alcohol lessens the absorption of oxygen by the blood corpuscles and the exhalation of carbon dioxid. Alcohol has a peculiar affinity for, at least manifests itself in changes of, the minute nerve terminations of the periphery. First, there seems to be swelling, infiltration, with leucocytes and fatty granules of debris, then thickening and inflammation, followed by degeneration and wasting of the nerve and muscle fibers. In optic neuritis, the interstitial tissue is first affected. Dr. Wilkes shows that alcohol affects the tubular and vesicular neurins by dissolving the phosphorus and protagen, and shrinking and hardening the nerve fibers. These conditions are alcoholic neuritis, and the impression prevails that it is largely due to retained products of metabolism and atheromatous degeneration of the walls of the vessels. The continued use of alcohol is followed by profound degeneration of the cells and nerve-trunks. The brain as a whole is shrunken and contracted, and serous effusions fill the spaces. The cells are also shrunken and wasted, and the nerve fibers and cells are atrophied and mixed up with connective tissue, which grows enormously.

The stomach is eroded, and contains patches of inflammation with increase of connective tissue and atrophy of the gland-cells. The liver also shows inflammation of the parenchyma and proliferation of cells and leucocytes blocking up the spaces. The kidneys show the same cumulations of the products of metabolism. Dr. Glaser proves that alcohol in moderate quantities irritates the kidneys and the augmented leucocytes, cylinders and crystals, being due to the increased metabolism of the tissues or to the alteration by alcohol of the relations of the solubility of the urine salts. The heart becomes fatty and its power enfeebled; the muscular fibers degenerate and lose their uniformity, becoming swollen and atrophied; the walls of the blood-vessels are thickened or thinned, become atheromatous and lose their resiliency; the lungs suffer atrophy and the tissue degenerates; local inflammation and irritation are present. In all cases, the use of alcohol in any form is followed

by a diminution of the white-blood corpuscles or leucocytes and a diminished resistance to every condition of strain, drain, fatigue, and every form of environment which taxes the organs to adjust itself to the new conditions. Alcohol given to animals in small doses, and under various conditions has the same effect. The study of the cells and nerve fibers shows identical changes, confirming the facts mentioned. Dr. Van Gieson of the New York State Pathological Institute has pointed out the action of alcohol on the cells as erosive, breaking up the normal relation of the granular or protoplasmic matter, and corrugating the fibula dentrites. He concludes that this is dynamic and nutritive, and is cell-disturbance and cell-starvation. The function is changed and its nourishment is lessened.

A great variety of facts have been accumulated relating to the immediate action of alcohol on the body. The following may be stated as the most reliable, and generally accepted as proven: The rapidity of the absorption of alcohol is shown to be such that within a minute and a half from the time alcohol is taken in the stomach it can be detected in the blood by chemic analysis. This rapid absorption is followed by a sense of warmth, which is not clearly explained, but in all cases it is due to both vasomotor and vasoconstrictor paralysis, also to the rapid absorption of water from every tissue it comes in contact with. The capillaries are dilated, and the heart action is increased but lessened in power. The blood is changed, the white corpuscles being lessened both in number and rapidity. Careful analyses show a marked diminution of carbon dioxid after alcohol is used. The most pronounced effect from the use of alcohol is sensorial palsy. Careful measurements of the senses before and after the use of alcohol show diminution of the acuteness and the activity of the senses. This goes on to full paralysis. The mental operations are slowed and diminished and can be measured exactly. Memory, reason, perception, and all the higher qualities are enfeebled according to the amount of alcohol used. In some cases one or two drams of alcohol will show marked effects; in others a large amount is required to show this by instruments of precision. But in all cases a degree of paralysis is present which may center on some part of the body more than the other. The conclusion which is sustained by all these and many other observations is that alcohol is a poison and a paralyzant in its effects on the body. This latter action is an explanation of its peculiar fascination to all persons in all circles of society. It is an anesthetic, stopping pain, discomfort, and psychic unrest, and creating a false impression by covering up the cries of distress and the protests of nature. The defects of growth, nutrition, disease, and every stage of living, find a seductive narcotic in alcohol. Later, the degeneration becomes fixed and settled. The demand for alcohol is often a symptom of some central defect in the brain and nervous system—the same want or desire for relief, as after the body is saturated with poison, only varying in degree. The ethers of alcohol are the most wonderful sleep and pain-numbing forces known. This same anesthesia is a property of all alcohols, with the addition of other pronounced effects. It is a startling fact that all the theories current of the food, tonic, stimulant and medicinal powers of alcohol have no support from modern research. On the contrary, it is found to be poison of equal virulence

to syphilis and other poisons. Recently alcoholic toxins are beginning to be studied, and the new facts appearing in this field promise some startling discoveries. A grouping of some of these facts may be stated as follows:

1. Alcohol acts primarily on the nerve-cells, changing their granular matter, breaking up their nutrition and changing their dynamic force.

2. This action is followed by contraction of the dendrites, swelling and atrophy of these fibers, also shrinking of cell walls, as in fatigue, and coalescing and disappearance of the granular matter of protoplasm.

3. The special injury from alcohol seems to be on protoplasm and terminal fibers of nerve trunks. The irritation and inflammation of the nerve walls and fibers ending in sclerosis are common.

4. Alcohol acts on the leucocytes of the blood, checking their activity, and destroying their function. These are driven in masses by the increasing rapidity of the heart, and become blocked up in the capillaries, forming centers of obstruction and injury.

5. The use of alcohol is found to be followed by diminution of the carbon dioxide and all waste elimination, with a marked sensorial palsy of the senses, and a slowing up of all the mental operations. These are the results of measurements with instruments of precision, and cannot be mistaken.

6. The action of alcohol in the light of modern research differs widely from the theories and current beliefs of the day.

HEREDITY AS A CAUSATIVE FACTOR OF INEBRIETY.

Presented to the Section on State Medicine, at the Forty-ninth Annual Meeting of the American Medical Association, held at Denver, Colo., June 7-10, 1898.

BY F. C. MYERS, M.D.

KALAMAZOO.

That heredity is a common cause of alcoholism, and that alcoholism is a disease, is becoming apparent to many medical men of the present day.

In that good old book, the Bible, we are told that "The sins of the parents are visited upon the children to the third and fourth generations." That has been proven to be a fact, in the evil effects produced upon the system by the use of alcohol; the person whose brain and nervous system have been injured, and whose moral and will powers have been weakened, and whose stomach, liver, and other organs have become deranged by the use of alcohol, will transmit some of these derangements to his offspring.

The modern study of the therapeutics of alcohol has proven, without a doubt, that it is not a stimulant or tonic, but an anesthetic and a narcotic, and that it should be classed, in our works on therapeutics, as one or the other of these; and it has also been proven that it is a remedy of but little therapeutic value and one that could be dispensed with, even for medicinal purposes, with universal benefit to mankind. It is not my purpose in this paper to discuss the therapeutics of alcohol, but to prove, if possible, that the influences produced by alcohol are handed down from generation to generation.

The principles of heredity must have been known in ancient times, and undoubtedly gave rise to family names among the Romans, and in the present age the Bourbon nose and the Hapsburg upper lip are well-

known family characteristics; while some families are characterized for such virtues as business integrity, truthfulness, temperance and frugality, others are as equally marked for dishonesty, mendacity and drunkenness. A marked physiognomy and proneness for commercial pursuits have been Hebrew characteristics from time immemorial. The transmissibility of an alcoholic inheritance has been very generally admitted by many writers, among whom are Aristotle, Darwin, Rush, Morel, Grenier, Carpenter, Richardson-Thompson and Forel. The number of cases in which an ancestral history of alcoholism has been traced is probably much below the actual amount, as it is difficult to get relatives to admit the existence of an alcoholic taint. It has been found by studying the subject, that the proportion of hereditary cases has increased 5 per cent. over the acquired during the past twelve or fifteen years. Norman Kerr says: "In over 3000 cases of chronic alcoholism I have found fully one-half with an inebriate ancestry," and about the same proportion has been the experience of others who have studied the subject in America and Europe. Kerr again says: "I have observed children born more than a year after the father had been attacked by a brain disease or inebriety, exhibit from their earliest years propensity for intoxication, and in more than one family the children could, only by constant supervision, be kept from strong drink as soon as they began to crawl." And he says also: "Nearly two-thirds of the cases of inherited alcoholism are due to the alcoholism of one or both parents." I believe it has been fully proven that the child of an inebriate, born after the lesion has been established, inherits some nervous diathesis, and that the only security is by life-long abstinence on the part of the child. Beran Lewis attributed 64 per cent. of cases of chronic alcoholism to parental inebriety, some form of transmittal neurosis, or insanity. Piper puts the proportion of hereditary to acquired cases as 2 to 1.

In the examination of two groups of ten families each, in a children's hospital of London, one group of 57 was affected more or less by alcohol, the other of 61 was unaffected, or slightly so. Of the first group 20 had inebriate fathers, the mothers and grandparents being moderate drinkers; only 45 per cent. of these had healthy constitutions; 31 had inebriate fathers and grandfathers, but temperate mothers and grandmothers; only 2 of these, or a little over 6 per cent., were healthy. Of the 61 children belonging to the temperate families 82 per cent. were in good health.

The customary drinking of light wines and champagne at banquets and public dinners has been thought by many worthy people in the past, to be perfectly harmless, but as more light is thrown upon the subject of heredity and the therapeutic action of alcohol, that custom will gradually be abandoned; in fact, it is becoming less customary at the present time. There has never been a time in America when every indication pointed so strongly to a decrease in intemperance as at present. There has never been so little drinking as at present, and never such a strong tendency toward moderation in quarters where alcoholic indulgence is general. The most careful figures bear out this statement. That hereditary craving for strong drink can be transmitted by parents who have not that craving, but who drink very moderately, has been proven. Forel says (*Medical Pioneer* of December, 1893): "Hereditary crav-

ing for alcohol may proceed from parents neither of whom possessed this craving, but were drinkers only by custom or sociability."

Not being connected with any inebriate institution my experience is limited to that of a general practitioner, but a typical case came under my observation a few years ago. A man, born and educated in Edinburgh, Scotland, whose parents were wealthy people, but who had been in the habit of using light alcoholic drinks in the form of wines—as many Scotch families do—came to this country, entered business, and was a very bright business man and honest in all his ways, but from every month to three months—never going over three months—he would leave everything and enter upon a drunken spree. It made no difference how much was involved in business interests. As he was under my observation for two or three years, I know that it was against his will and purpose, and that he made every effort to overcome the hereditary power that was controlling him. It was usually from two to three weeks before he was ready for business again. He was a person of much moral purpose and great business integrity when himself, and has told me many times that he always had a periodic craving for alcohol ever since he could remember; he had one daughter born to him who is a nervous uncontrollable child.

Another case of a bright young lady was under my observation for a year, who, every few weeks, from her earliest memory, had such a craving for alcohol that it seemed impossible to resist it. After taking a few swallows of diluted whisky she was satisfied, the craving for it ceased and her nerves became quiet. As she was a person who never had been in the habit of drinking, only in this way, the craving was undoubtedly from a hereditary source. Many other cases might be referred to, but as there are those here who have made that subject a special study and who would naturally see many more cases of the kind than a general practitioner, that part of the subject will be left for their consideration.

In conclusion I would ask: If one of the principal causes of inebriety is heredity, how is this form of inebriety to be cured and our future generations saved? I know of but one way, and that is to stop the drinking habit at once. As it has been proven that: 1, alcohol is not a food; 2, it does not promote digestion; 3, it does cause gastric disturbances; 4, it does not increase muscular strength; 5, it is not a tonic or stimulant, therefore I believe medical men ought to do all in their power to educate the rising generation in regard to these facts, and that alcohol should be classed in its proper place—with anesthetics or narcotics—and everything possible done to prevent its universal use as a common beverage in social and political life. By so doing inebriety may be practically wiped out of existence in one generation, and a blot removed from this fair earth of ours, which would be an untold blessing to thousands of families.

Rest in Chorea.—Van Bibrer reports twenty-five children cured of chorea during the last year by keeping them in bed, the muscles arranged in the manner most conducive to repose, with conscientious massage three times a day; the diet nutritious and abundant. Medicines can be given if desired, as the patient is in the best condition to take them. Rarely was he obliged to keep the child in bed over a month.—*Journ. de Méd. de Paris*, October 20.

ISOLATION IN A GREAT CITY, HOW BEST ACCOMPLISHED.

Presented to the Section on State Medicine, at the Forty-ninth Annual Meeting of the American Medical Association, held at Denver, Colo., June 7-10, 1898.

BY SAMUEL P. DUFFIELD, M.D.

EX-CITY HEALTH OFFICER.
DETROIT, MICH.

Subsequent to the fourteenth century, when the plague passed that gate of quarantine between infected districts and the civilized nations, *the world began to think*. Physicians and chemists turned their attention to *causes* of disease, and from the advanced knowledge obtained boards of health were developed. It was found that pecuniary loss from sickness and pestilence was so great that steps were taken to guard against the spread of contagious disease, and the laws of the land in regard to public health have gradually and surely developed into a system which has been successful in warding off these diseases and preventing serious epidemics. This was the first tree, tender and young, which, planted in the gloom and despair of a plague-stricken people, bears fruit today, "for the healing of the nations."

Our health laws and ordinances, pestilences and plagues have been great reformers. Old Pharaoh was no believer in bacteriology. He was like the third-class criminal lawyers, who like a *Bombastes furioso* in their pseudo-eloquent appeals "about the inalienable rights of the American citizen" to a jury that do not know what a bacillus or a bacterium is, and who can not see the use of such things in everyday life, because they are "practical men" and believe in "common sense," and see no reason why they should adopt every fad the doctors choose to "force upon the public." For his neglect of studying the laws of nature, Pharaoh's kingdom was overrun with pestilences of various kinds, and finally preserved for future reference in brine, to which, metaphorically, we would also consign the ignorant third-rate criminal lawyer who sometimes manages to be appointed as health commissioner, claiming he is a practical man.

Contending with such difficulties as have been foreshadowed, the local health officer finds it difficult to even enforce the municipal ordinances, as the sympathy of the jury is usually in favor of the "poor man, who did not know any better," and who has, in their opinion, "suffered enough already," even if he has brought it upon himself by gross carelessness. But in spite of the above obstacles there has been an advance along the line, by local health officers. Since the introduction of antitoxin we have reduced the mortality of diphtheria, as the following statements will show: Diphtheria is most prevalent in cities. During the last twenty-five years it has become epidemic in most of the larger cities in the Northern and Western States, from the Atlantic to the Pacific coast, following the lines of travel. The permanent establishment of diphtheria in the centers of trade, and the fact that many grown people have this disease in so mild a form that they are not aware of it, and innocently mingle with others in places of amusement, inevitably tend to disseminate this disease throughout the country.

In Europe it has boldly established itself, even in centers of medical education. In Paris, London, and Vienna it has been of late the subject of much discussion and investigation. In Europe and America the literature of diphtheria has greatly increased dur-

ing the past ten years, by reports of cases, histories of epidemics and statistics of results of different modes of treatment.

The fact that diphtheria virus can be carried in clothing long distances without losing its virulence is now generally admitted by those who have made many and careful observations. Trousseau has said that diphtheria does not spare any age, but it is most common between the ages of two and six years. Observations which I have made during the years 1895-1896, and cases and deaths which I give in tabular form below, show that up to the age of 9 years in the year 1896, 90 per cent died, while from 10 years on to 74, there were only 10 per cent. of the total deaths of diphtheria. According to M. Barthez, in St. Eugenie Hospital, during twenty years, the ages of diphtheria patients were as follows:

AGE.	CASES.
Under one year	81
1 to 2 years	314
2 to 3 years	319
3 to 4 years	292
4 to 5 years	200
5 to 6 years	103
6 to 7 years	59
7 to 8 years	36
8 to 9 years	59
9 to 15 years	82
15 to 17 years	2
Total	1547

The total number of cases from under 1 year to 17 years, inclusive, is 1547. From under 1 year to 8 years we have 1404 cases, and from 8 to 17 years, inclusive, there were 143 cases. Hence,

$$1547 : 1404 :: 100 : x = \frac{140400}{1547} = 90.7$$

90.7 per cent. of the cases occurred from under 1 year to 8 years, while

$$1547 : 143 :: 100 : x = \frac{14300}{1547} = 9.24$$

Only 9.24 per cent. occurred from the eighth year upward to the seventeenth year, inclusive.

Now take the death-rate as it appears in the city of Detroit and you will find that it follows closely the same rates.

MARCH, 1896, TO FEBRUARY 28, 1897.

AGE.	DEATHS.
Under 1 year	11
1 year	28
2 years	54
3 years	29
4 years	35

Total deaths from diphtheria 260

It will be seen that out of 260 deaths which occurred from March 1, 1896, to Feb. 28, 1897, 90 per cent. of the deaths properly chargeable to diphtheria were below 9 years of age; while from 9 years upward to 74 years the rate was only 10 per cent. You will perceive what havoc the contagion makes in the earlier years of childhood. The figures given above teach a peculiarly sad lesson. They show how carefully children of ages ranging from 1 year up to 9 years should be guarded. How sedulously gatherings of children, when coming from homes whose surroundings are not known, should be avoided. It would be well for ladies who send their children to kindergartens to weigh well these figures.

The home of every pupil of the kindergarten should be visited by a ladies' committee, composed of mothers, that they may know positively what influences may be at work from the individual scholar. The teacher of these tender little ones should be subjected to a scrutiny far more searching than the teacher of the higher grades. She should, in her mode of life and circle of acquaintance, be above all suspicion of coming from or visiting any house in which there is a case of sore throat, or any child suffering from a rash, or in fact, any sick child. Such a percentage of death should warn all mothers who can afford to do so, to teach their children at the mother's knee. I am aware from personal observation that there are many poor laboring women who have no time to devote to their children. It is unfortunate that this is so, as the mortality rate plainly indicates that the danger to children of 5 and 6 years is very great. This danger is not confined alone to diphtheria, but is apparent also in cases of scarlet fever. You will notice from the figures on that disease, which I give below, how nearly the same percentage runs through the years from 1 to 8:

AGE.	DEATHS.
Under 1 year	1
1 year	2
2 years	9
3 "	2
4 "	6
5 "	4
6 "	3
7 "	2
8 "	1

From under 1 to 8 inclusive 30

$$33 : 30 :: 100 : x = \frac{3000}{33} = 90.9 \text{ per cent.}$$

That is, from 1 year to 8 years, inclusive, the death rate is 90.9 per cent.

AGE.	DEATHS.
12 years	2
13 "	1

9 years upward 3

$$33 : 3 :: 100 : x = \frac{300}{33} = 9.09 \text{ per cent.}$$

From 9 years to 13 years and upward only 9.09 per cent. of the total death-rate for scarlet fever died.

During the year 1896 antitoxin was used as a remedy, and through observation and tabulation of the cases and deaths in the city of Detroit we find a death-

rate of 12.58 per cent. where antitoxin was used. May 1, 1896, the Board of Health of the city of Detroit began furnishing antitoxin free to those patients too poor to pay for it. This included poor patients under charge of the city physician; poor patients at Harper Hospital, sent there by the Board of Health; at the Women's Hospital and Protestant Orphan Asylum. Total diphtheria patients treated with antitoxin were 374, with 47 deaths. Total doses for immunizing, 119. Failure to immunize, 25. There were dispensed 643 doses, representing 493 patients, a seeming discrepancy of 150 doses. This is accounted for by the fact that in many cases two and sometimes more doses were given to one patient.

	CASES.	DEATHS.	MORTALITY RATE.
Antitoxin	374	47	12.56 per cent.
Other treatment			
Without antitoxin	467	163	34.90 per cent.
Percentage in favor of antitoxin, 23.34.			

The total cost of antitoxin for these cases was \$1,234.45.

TENEMENT HOUSES.

I would call attention to the fact that in building tenement houses, they are constructed in such a way as to defeat any efforts in attempting effectual isolation. Ordinary houses are rented and occupied by several families, sometimes as many as four. There should be some remedy. Whenever a case of contagious disease develops in such a building it becomes our duty to placard and place in quarantine the family in which the disease occurs. This may seem a very easy problem to solve, but it is in reality one of the hardest that the Health Board has to grapple with, for several reasons. *Isolation can not be perfectly maintained.* More than one family occupies the house. Those families in which there is no sickness can not be quarantined; and all we can do is to seal all entrances to a common hall, so as to prevent them from mingling with those not in quarantine. An economic council or board of aldermen consider it too expensive to have guards or inspectors. It costs the people too much.

Our inspectors are asked, by those who realize the fearful danger from diphtheria, why the health officer does not order the case to the hospital. They are informed that if the patients are willing, the health officer will send the patient to the hospital, at the expense of the health department. It may be that the patient is a little child, a mere babe, and the mother inquires if she can accompany her babe. On being informed she can not, as the hospital authorities will not allow it, she refuses point-blank to allow the child to be taken. She will stay at home with the child and nurse it, endangering the other children, simply because she will not allow the child to go to the hospital. It must be apparent that for the tenement-house patient, the Board of Health should make an arrangement by which we could have cottages of refuge for diphtheria, and also for scarlet fever cases. I find by conversation with mechanics and their wives that they would gladly avail themselves of such a place, were they assured that one of the parents, preferably the mother, could accompany the child. The father, in case the mother refuses to let the child go to the hospital, must have his house quarantined, and if he wishes to continue work he must board away from his infected house. Under the "Cottage of Refuge" system he could come home to the remainder of the family at night, to a home which has no infection

in it, and from which he goes on the morrow to work, without danger of infecting other people. There is no germ to be carried in his clothing.

I have often been met with the remark, "Why not force the father and mother to give up their child and take it to the hospital for the benefit of the community?" The sanitarian who says that on paper would feel differently if he were to individually put it to a test. There is nothing in the world so strong, so clinging, so self-sacrificing, so self-denying, so beautiful in its freedom from selfishness, so bold and courageous in the defense of her babe, as the love of an anxious mother. Fearful sometimes themselves, of the terrible pestilence which swept Detroit city only two years ago, when told that the child had it and must go to the contagious disease hospital, they refused to allow it to be taken to the ambulance unless they could accompany it. I took always one of the parents, sometimes it was the mother and sometimes the father. I usually let them decide that question between themselves, husband and wife, as to who should go with the child to the smallpox hospital. My experience with these people has led me to realize that unless we allow the mother to go with the child, we will fail in the majority of cases, for the reasons given above.

What is true of smallpox is equally true of diphtheria. Tenement houses are the hotbeds where virulent forms of diphtheria are cultivated, and from these culture-beds the poison is spread through the city. It reaches the homes of splendor and luxury from just such places, from cases which are not known until the death certificate comes in, signed by the physician, "Called in just before the child died." The cottage refuge system would relieve this state of affairs materially. In order to carry out this system satisfactorily, the Board of Health should be untrammelled by *political* appointments, either on the board itself or among its employees.

THE RIGHTS OF THE PUBLIC IN DEALING WITH THE DEFECTIVE CLASSES.

Presented to the Section on State Medicine, at the Forty-ninth Annual Meeting of the American Medical Association held at Denver, Colo., June 7-10, 1898.

BY ALFRED WILMARTH, M.D.

SUPERINTENDENT OF THE WISCONSIN HOME FOR FEEBLE-MINDED.
CHIPPEWA FALLS, WIS.

The care of the dependent classes has been a matter actively before the public for many years, and in its rapid evolution has now assumed such proportions and carries with it such enormous expenditures that its growth and possible curtailment are questions of grave importance. We can justly pride ourselves on the admirable system and vast extent of our charities, but we can not but realize that they constitute a tax of no small importance on the income-earning portion of our population.

The last census states the number of blind in the United States as 50,411, of deaf and dumb as 80,616, of feeble-minded 95,571, and of insane as 106,254. The two first-named classes are not wholly dependent, and are very often entirely self-sustaining, and money spent in their education is well spent. The classes who nearly or entirely live on the public are the insane and imbecile, the pauper, habitual criminal and the tramp.

The treatment of the pauper and the tramp belong more properly to the sociologist and local magistrate

than to the physician, although they merge into the other classes in such a way that there is no sharp dividing line. It is to those dependents whose condition is due to physical degeneracy or diseases that I wish to particularly call your attention.

The census report on the insane gave the total in round numbers for the country at 92,000 in 1880, and 106,000 in 1890; for the feeble-minded at 76,000 in 1880, and 96,000 in 1890. It is probable that the enumeration of the insane may be far more accurate than that of the feeble-minded, as the higher grades of imbecility are often not recognized or at least not acknowledged by relations, and past investigations have shown that a large proportion of these are not acknowledged to census officers. Even with these figures we have over 200,000 in these two classes. At an average weekly cost of \$2.50 a week, which is probably an underestimate, the actual money cost of their care amounts to over \$2,000,000 each month. To this must be added the cost of the care of the habitual criminal, the dependent children, the vagabond and the habitual drunkard. So varied are the demands for the support and relief of all the dependent that we find that the New York State Board of Charities expended nearly eight and a half millions of dollars in 1880, and nearly sixteen and a half millions in 1890, although the population of the State increased less than 20 per cent. in that decade. And this startling amount represents the expenditure in one State only. These few figures demonstrate, as well as many pages could, not only the burden which rests on the more thrifty and stronger members of our community but also its constant increase. Carry these figures through the many States of the Union and realize their enormous total.

If we look closely into the lines along which this army grows we will begin to see at once that certain families contribute very largely to the total. The history of the "Juke" family has been often quoted. I took occasion two years ago to call your attention to the history of "Margaret, the Mother of Criminals," whose progeny of paupers, beggars, prostitutes and criminals reached 700, their family vigor being preserved by intermarriage with vigorous families of ruffians, some of the women bearing as high as twenty children. I also referred to the "Tribe of Ishmael," where the offspring of one neurotic man intensified by consanguineous marriages numbers some 5000 individuals "whose continued criminal record has poured over the Northwest a flood of imbecility and crime." I want to add to this a family recorded by Prof. Belman of the University of Bonn. They are the offspring of a notorious drunkard who died in 1800. His descendants number 834, of whom 709 were traced from their youth. Seven of these were convicted of murder; 76 of other crimes; 142 were professional beggars; 64 lived on charity, and 181 of the women of the family lived disreputable lives. The family cost the German government for maintenance and costs in public institutions \$1,250,000—in other words, \$1,500 each. These are extreme instances, but instances on a smaller scale may be found by any one who cares to look for them. I now have a family in mind where there are seven children, all feeble-minded, and the daughters are bearing illegitimate children to form a third generation of weakness, perhaps crime.

The vast majority of authorities testify to the truth of the transmission of ancestral characteristics as

shown in these examples. Through the channels of transmitted nervous weakness and inherited moral taint the vicious stream flows and multiplies. Checked somewhat in its course at times, but not fully eradicated, it will resume its flow whenever conditions are favorable. To show the persistency of the degeneration, it sometimes happens that a feeble-minded woman will bear children by several different fathers, and all will present the mother's weakness, sometimes intensified. With such proof that neurotic weakness is directly transmitted in all its forms; with the knowledge that this heritage has been accumulating for perhaps several generations, we can hardly expect it to disappear in a brief period of education, or a sound mental and moral condition to be created from a weak one in any limited time. Education may do much for them in the way of increasing their power of self-support, but can never eradicate the characteristics which are their birthright and which are bound to pass from them to their children, to lie dormant if their surroundings be fortunate, or to readily spring into activity under the stimulus of unhealthy surroundings or example. Now, is it not wise that such individuals should die without increase, allowing healthier stock to perpetuate our race?

I have dealt at some length on the money cost in their support, but that is not the only evil incident to their existence. Their evil example is always before the children of the community. The insane man or woman is, furthermore, a constant menace to the safety and even the lives of our citizens. Look up for one month the number of assaults and murders committed by the insane and his near relative, the drunkard. The murder of whole families is not so infrequent, and the awful murder of Terriss, the actor, by the eccentric Prince is only one of many crimes which come like the lightning-stroke from those who have been regarded as amusing subjects for sport or avoided as bores from their inordinate egotism.

The family whose members have not sufficient intellect to establish a decent support for themselves and not sufficient moral strength to refrain from petty crime is a neighborhood nuisance, as any one can testify who has lived neighbor in their vicinity. How shall the rights of the public be sustained in this matter? For the little ones, the numerous child-saving institutions are at present doing a great work, placing the children among good surroundings and giving them every advantage of development. A certain proportion of these waifs can not develop, and they come back upon the public for care. For such persons as are definitely determined to be permanently defective we have three radical methods to prevent further increase: 1, sequestration; 2, prevention of marriage; 3, surgical interference. In many ways the public has taken the ground that the welfare of the many shall take precedence over the liberty of the few. The man who unlawfully takes his neighbor's property, even in small amount, is promptly imprisoned. The insane man becomes dangerous to his neighbor or himself, and is confined until danger from his being at large is supposed to be removed.

The man who wilfully inflicts bodily injury on his neighbor is taken in hand by the law, and conditions placed over him to prevent his doing so again, either by a money fine or imprisonment; or he may be placed under bonds, or imprisoned, if it is known that he intends to repeat his offense. On the other hand, a neurotic man may marry a neurotic woman and

bring into the world nine beings, as I have stated, to live a lifetime of suffering. An insane man may go home to his family during his better periods from a hospital and resume his family relations and cause the birth of other beings, who stand much more than a chance of a miserable life. And in very few States is this discouraged.

The imbecile may marry, and marry pretty often, and the taxpayer supports the fruits of such a union, often with money that represents much self-denial, and perhaps should be spent in the better education of his own promising offspring. A woman recently wrote me, "My husband died, and as I had *no other means of getting a living*, I married again. That man left me and I have married another!" She wished to dispose of her imbecile boy.

As I have already said, there are three methods of meeting this evil. 1. The woman may be sequestered. The question of "personal liberty" may come up here. But personal liberty is not desirable when it can bring nothing but harm to its possessor. Let the imbecile woman gratify her maternal instinct of caring for the little ones in caring for the little children in an institution. The bearing of children, when it is only the fruit of passion, without any adequate sense of the responsibilities entailed, should never be. It is no especial hardship for any defective woman to spend her life in a modern institution with every comfort furnished her and with congenial companionship. She loses only responsibilities she is unfitted to assume, and escapes dangers of which she has no adequate conception. Such a step ends her danger as a multiplier of her own weakness, and the present rapid increase in our dependent population would at once diminish.

2. The passage and enforcement of more stringent marriage laws. Laws have been passed in several States to this end, imposing a large fine on those who will, for a larger or smaller fee, perform the marriage ceremony in such cases. With the State caring for the women who have not the mental or moral strength to care for themselves, and the law preventing the marriage of those known to be insane, epileptic or habitually criminal, the production of the unfit will surely be greatly controlled and the public far less alarmed when the great number and cost of support of the dependent is brought to light.

3. The adoption of surgical measures for the prevention of the further increase of such defectives as threaten to be a life burden is coming more and more into prominence. It has been boldly advocated by some prominent in the work. Few men, when their attention is earnestly called to the matter, can urge any very strong objections against it. It would not be necessary, if it were possible to fully carry out the idea of sequestration and prevention of improper marriages to complete success, but neither of these provisions are so surely effective as this radical measure.

The farmer knows that he can exterminate the weeds most thoroughly from the ground, which should bear only life-supporting grain, by seeing that they do not seed. For those who with no right to have offspring, yet will offend against both morality and law, the surgeon may yet be called upon to follow the example of the farmer, and by operating, guard society from the contamination and burden of the increasing number of those whose lives should never be begun, and by a comparatively safe operation make parentage impossible. The public are not thoroughly

alive to this matter, simply because they are unable to see the evil in its aggregate importance, and when they do awake to its magnitude much sentiment will be replaced by earnest, business-like methods of suppression and control. The time may even come when continuous births of defective children in one family may be thought of sufficient gravity for a forced separation of the parents. The idea of nine helpless ones being born into a community does not seem consistent with modern civilization. Yet I know of two families where such a tragedy has occurred, and many more where from three to seven have been born.

I have ventured to bring this subject before you again because it is one of the great social problems which lie largely in our province to solve, and to which it is our duty to give our most earnest thought, and I ask for it your aid, if on mature thought you find that the views here advanced lie in the line of true reform.

THE WATER-SUPPLY OF CITIES.

Presented to the Section on State Medicine, at the Forty-ninth Annual Meeting of the American Medical Association, held at Denver, Colo., June 7-10, 1898.

BY C. F. ULRICH, A.M., M.D.

WHEELING, W. VA.

This is one of the burning questions of the hour. It is not because there is a lack of water. We have an abundance of streams, from the smallest brook that rushes down the mountain side, meanders through the fields and meadows, between flowery banks, over gravelly beds or through rich soil in cultivated bottom lands to the great Father of Waters, fed by the hundreds of streams permeating the immense territory spread out in magnificence between the Alleghenies on the east and the Rocky Mountains, rearing their lofty summits to the sky on the west. This vast system of streams carries the almost unlimited supply of water that falls from the clouds, by day and by night, down to the boundless ocean, rendering the magnificent valley of the Mississippi the fairest, loveliest and most productive portion of the surface of our terrestrial sphere. We have that immense chain of lakes from Superior to Ontario—that beautiful system of inland seas that divides the "Land of the Free and the Home of the Brave" from the British Possessions on the American Continent.

We can not, therefore, complain that, in a general way, there is a scarcity of the aqueous fluid; although when the burning summer sun pours down his scorching rays upon the thirsty surface of the earth, the rains cease to fall, the brooks dry up, the creeks diminish in volume, the rivers grow narrow and shallow, not permitting boats to navigate them, and in places even becoming fordable. Yet, in the main, there is water enough in the streams to supply the wants of the population living upon or near their banks.

What is it, then, that makes the question of the water-supply such an urgent one, causing so much complaint, so much anxiety; giving rise to so much contradictory legislation? Sixty years ago we heard nothing about the water troubles. People had their springs or wells, from which they procured water for drinking and cooking, while for washing and cleaning they would catch rain-water in barrels and cisterns, or they would haul water from neighboring streams, leave the barrel standing near the house until the supply was exhausted, and then make another trip to

the stream. Even now, in some antiquated cities of Southern Europe, Asia and Africa, there are water-carriers, who supply the population with water, hauling it in a cart, carrying it on the back of a mule or donkey, or even on their own backs. With the modern ideas of comfort, convenience, cleanliness and health such primitive means of supplying water would be absurd. The population of the earth has increased at an enormous rate during the last century, and the general tendency has been to congregate in cities; so that now a city numbering less than 100,000 inhabitants is counted little better than a village, and several cities number their inhabitants by the millions. Now the problem of furnishing such immense accumulations of people with a sufficiency of water for all uses becomes much more difficult than a superficial observer would imagine.

There are conditions essential to make the water-supply of a large city what it should be, and in many places, one, or even two, of these are wanting, while in some even all three are deficient. These conditions are: a sufficient quantity for all possible emergencies; clearness, i. e., apparent purity; and healthfulness, i. e., freedom from disease germs.

Let us first consider the question of quantity. There is a vast increase in the amount of water used now over that used fifty years ago by the same number of people. Why is this? Do they drink more? No. Do they wash more? Probably; because they have made some progress in cleanliness. Have they more cattle and horses to water? No; for steam and electricity have diminished the demand for horses; and the number of cattle, in proportion to the population, has not been increased.

Let us see what has caused this great demand for water in excess of what was formerly required. In every densely populated city the sources of disease are necessarily increased. The air is contaminated where people are closely crowded together. How that can be corrected by the copious use of water will be explained farther on. The excreta of men and animals contain much that is unhealthy, even when not charged with disease germs. This necessitates much water to remove them and clear away their traces from the places where they were deposited. The streets want to be cleaned, the alleys and stable-yards cleaned out, the sewers flushed. A variety of apparatus must be employed to remove filth, which either contains the disease-producing bacteria or forms a good nidus for their propagation; all of which requires large quantities of water. But there are other causes for the increased demands for water, as, for instance, machinery. Half a century ago, much of the manufacturing was done by hand, which required but little water. Now we have steam-engines for driving all sorts of machinery, and for putting electric dynamos in motion, also water-motors; all of which use up great quantities of water.

The water-motor especially, in which class is included the thousands of elevators found in every city, consumes enormous quantities of water. Formerly the merchants had buildings two or three stories high, and when they wanted to go to the upper part of the house they walked. Now their buildings are from six to ten stories high; and the sky-scrapers, built principally for offices, reach the enormous height of twenty to thirty stories. Now, how do the occupants ascend to these dizzy heights? It is by means of elevators or lifts, which are run mostly by water-

power, and some by electric motors. Every restaurant and saloon has a motor to bring provisions from the kitchen, beer, ale and wine from the cellar, to run the fan in the summer to enable the customer to keep cool, while being heated up with the drinks they take, and for many other uses.

The average citizen knows very little of how much water is required for such purposes. I never had the least idea of the enormous quantities of water that are consumed until I became a member of the water board. Then there are the fires that occur in large cities, where whole blocks and sections would be destroyed if the fire department with its vast consumption of water did not come to the rescue. In order to preserve the health of the city, frequent cleaning of the streets and flushing of the sewers are necessary. The sprinkling of the streets done by individuals in front of their houses, although consuming a good deal of water, does not contribute much to the cleansing of the city. This work, in order to be effective, should be done on a large scale by means of the fire-hose, which prevents the dust, charged with disease germs, from rising and exposing all who breathe the dust-laden air to the danger of contracting disease.

In order to meet all these wants it is essential to have reservoirs large enough to hold a sufficiency of water to supply the city for at least a week. For, if any accident should happen to the machinery to disable it for several days, and the reservoir is too small, great suffering would be entailed on the city. When the citizens of Wheeling, W. Va., my home, were informed that our reservoir, which they had always believed to be ample for our wants, had to be filled from two to three times in twenty-four hours to keep the city in water they were thunderstruck, requiring a sight of the daily records of the waterworks to be convinced. If the waterworks are owned by the city, as is the case in Wheeling, the city fathers would see to it that a sufficiency of water is provided to meet any such emergency. In our case, the city council, not seeing their way clear to spend the large sum necessary to build a new reservoir, sixteen or seventeen times as large as the one we now have, did the best they could under the circumstances, giving the water board permission to establish a new pump of sufficient power to keep the city from a water famine in case of accident; kindly permitting the board to pay for it out of the receipts from the water rents. Should a stock company own the waterworks, the city government would either compel the company to provide for all contingencies or would annul their charter and establish a pumping station of its own, unless they had been foolish enough to grant a perpetual charter.

Another advantage of a large reservoir is, that it affords facilities for connecting a filtering apparatus, which brings us to the second part of our subject—clearness of the water. Although filtering does not clear the water entirely of disease germs, it does so to a great extent; for they are more apt to attach themselves to the solid material that is found in the water. Besides, filtered water has a decided advantage over that pumped directly out of the stream. It is more palatable and more pleasant to drink; it does not nauseate you when you raise the glass to your lips and make you wish you had a glass of beer instead; it is better for washing clothes and cleansing of every kind. Besides, the filth that is found in the water during and immediately after a rise in the river brings

disease as well as disgust. I will not here enter into a discussion of the relative merits of the two great systems—the English or sand-bed filter, and the American or mechanical filter—that being a subject for an association of water boards rather than a medical association. Each one has its peculiar advantages and disadvantages. From the very limited investigation I have been able to make, I prefer the sand-bed filter, where a suitable location can be had, where the right kind of sand is easily accessible, and where money is not too scarce, because in this system no foreign substance is required, such as alum or similar substances, which are indispensable with a mechanical filter, for the purpose of coagulating albuminoids.

I will incidentally mention that a filtering apparatus, improperly cared for, is worse than useless. It would act simply as a store-house for filth and bacteria of every kind, which would remain in the filter. Then, when clear water passes through, it will be itself contaminated by the filth left in the filter from former masses of impure water that had passed through. Therefore, whenever a filtering apparatus is established in connection with a reservoir, ample provision should be made for cleaning it regularly, with special care after the occurrence of high water. When the plant is owned by the city, all these things can be attended to by the proper authorities, among whom the health officer, with his staff of assistants, should always be included; because a great many questions come up, in the management of filtering apparatus, that affect the health of the inhabitants. From the experience our little city of Wheeling has had, I would very strenuously advocate the city ownership of all the works pertaining to the water-supply; so that the city authorities may have entire control of the whole business. There is, however, one disadvantage in this arrangement. I mean the political favoritism that is shown in the selection of officials and operatives, which works harm to the service by handicapping them in the performance of their duty, they being to some extent subject to the caprice of the voters. Or, if they adhere rigidly to their idea of what is right, they are subject to being turned out on a change of administration, perhaps just in the midst of some important improvement they are about to carry into effect. Notwithstanding this drawback, which should not be permitted to exist and which could easily be prevented by establishing a civil service list of all officials and operatives whose frequent change would be detrimental to the service, the city ownership of waterworks, gasworks, electric street-lighting, etc., should, in my opinion, be insisted upon in every municipality.

There is one question arising here, which seems to me to be of considerable importance. I said, in the beginning of this paper, that only a small part of the water furnished to a city is consumed by families for drinking, cooking, washing, and other domestic uses. The great bulk of it is used for street cleaning, quenching fires, flushing sewers, running machinery; all sorts of motors, lifts, elevators, etc., which are propelled by water-power. It would seem to be a great waste of labor and money to filter water used for such purposes as that, from which no benefit whatever would be derived. My suggestion would be to filter only such an amount of water as is consumed for domestic purposes—drinking, cooking and washing—besides any fine mechanical work in the prosecution of which clear water is essential. This would

make a very great reduction of the expense of filtering, without invalidating its utility. But here the objector will come in and say: "How can that be done? Can you send filtered and unfiltered water through the same pipes?" Certainly not. You would have to establish two reservoirs and two separate systems of pipes: both to be supplied from the same pumping station. This would entail considerable expense at the beginning. But the great saving in the cost of filtering would, in a few years, wipe out the additional cost of reservoir and pipes. I throw out these ideas simply as suggestions to induce reflection and study on the subject, leaving it to specially trained minds to make the necessary calculations, and decide on the feasibility of the plan. The proportion of bacteria that can be removed from the water by filtering I am not prepared to determine, but I know that from 75 to 90 per cent. are claimed by various contractors. I believe that one firm has gone so far as to guarantee 97 per cent. If this is the case, which I am not prepared to assert, having made no microscopic examination of water before and after filtering, there would be very little more necessary to bring about the third condition; i.e., the purity of the water, or its freedom from disease germs.

So far as I can see, nothing more can be done by public works, and, if private consumers want a greater degree of purity, they must boil it in their homes after receiving it filtered from the waterworks. Many families have been boiling their drinking water for a number of years. But to boil unfiltered water renders it unpalatable, and generates disgust in the one drinking it; so that an unwillingness to drink water ensues, and many persons resort to beverages that are injurious, damaging the consumer both in body and mind. In connection with a filtering apparatus, an arrangement for aerating the water would be of great service. When water is entirely devoid of air, it tastes flat, lacking that exhilarating quality that makes water so pleasant a beverage, enlivening the tired laborer and making him prefer a cool draught of fresh, aerated, ozonized water to beer, or any other of the customary drinks consumed by the masses of laboring men, while it promotes the health and liveliness of children, improving their digestion, assisting in the assimilation of their food and causing them to grow up to be strong, healthy and happy men and women. The method of aerating the water in connection with the filtering process I am not prepared to discuss at present. I am, however, giving the subject some attention, and may possibly be able to furnish a paper on it and kindred topics on a future occasion.

How to prevent the pollution of streams from which the water-supply is taken, thus obviating and making unnecessary much of the labor and expense of which I have given you an imperfect description, is a subject of such vast importance and such almost limitless extent that I would not venture to bring it into this paper; having already reached the limit of time allowed. Should I ever feel within myself the ability to cope with that momentous question, I will come out with an essay on it at some future meeting. "Water: Its Uses, Benefits, Indispensableness and Purity" constitutes an inexhaustible topic for the medical writer, the sanitarian, the statesman; yea, for every father of a family, and for every housekeeper. An abundant supply of clear, pure, sparkling water, will contribute more to the health, comfort and hap-

piness of the human race than any other single article that could be mentioned. Every health board—National, State, city or town—every public official, whose position gives him authority in questions of that kind; every man of influence, who can prevail with those in authority, should strive with all his might to bring about a condition of things that would make good, pure water accessible to every one. The benefits to be derived from that state of things can scarcely be calculated. Water—the best and cheapest of all medicines, the promoter of comfort and happiness—should be supplied to every human being in abundance, in the best possible condition of purity, for the lowest available price that is compatible with the cost of procuring and furnishing it. The city authorities should not be penurious in providing this great promoter of health and happiness to all who live within their jurisdiction. For in spending money for this laudable purpose, they would be casting their bread upon the waters, which would return to them after many days, since the increased health and happiness of the inhabitants would add largely to the wealth of the city, and all would contribute to the general prosperity.

THE IMPORTANCE OF BACTERIOLOGY IN THE PROGRESS OF PREVENTIVE MEDICINE.

Presented to the Section on State Medicine, at the Forty-ninth Annual Meeting of the American Medical Association, held at Denver, Colo., June 7-10, 1898.

BY FRANKLIN STAPLES, M.D.
WINONA, MINN.

An English scientist has designated the present time as the "bacteriologic era." It has also been properly called "the period of preventive medicine." The reason and propriety of these appellations as together applied to the times, appear in the fact, that the more important advances made in medicine and surgery in late years have been dependent upon, or more or less connected with, discoveries and practical work in bacteriology. The names of scientists who have been and are now engaged in this work of advancement in different countries require no mention. It has been claimed that different characteristics in scientific and practical work have national or provincial origins and belongings; that, for instance, it was for German scientists, by patient investigation, to discover and furnish the foundation-material, to be utilized largely by practical workmen of other nations. In this country it is remembered when in medicine and surgery the making of books and scholars was accredited largely to Philadelphia, while New York and other places were given importance in the work of practical application. Whatever may have been true in the distant past, in the present outlook geographical limitations in science seem to be unknown.

STATE MEDICINE AT THE PRESENT TIME.

In the United States, as in other countries at the present time, preventive medicine is supported largely by the State. Aside from a humanitarian view, the value of human life to the State is considered, as well as that of property, and means are provided for the better protection and development of both.

The beginning of State preventive medicine proper antedates by a little time the coming of bacteriology as a science; but the growth of the former in the few years of its existence has been phenomenal. State

medicine began in England in 1844, and in the United States properly in 1889. Since then nearly every State in the Union has established health departments, each State having its local boards and officers, acting under laws more or less complete for the maintenance of public sanitation.

Various property interests have conspired to extend the limits of the domain of State medicine. The discovery of the identity of many diseases in man and animals, and the liability of the passage of infection in either direction, have given increased importance to veterinary medicine; and this, with the financial importance of loss from disease of animals, has largely increased the extent and importance of State sanitary control.

What has appeared concerning the existence and character of disease germs, their conditions of life, means of propagation, and behavior as specific disease causes, in other words, the pathology of germ diseases, has come to be the foundation of a large part of modern scientific medicine. Moreover, work in bacteriology in the last decade has not only widened the field of pathology, bringing into the possession of the world of science a new territory of vast extent and great value, but has pointed to possibilities in the future of preventive medicine, the extent of which may now be imagined but not fully estimated.

Concerning living organisms as causative agents in what are now known as infectious diseases, it has been aptly said: "It matters not whether the organism is large or small; whether it belongs to the animal or vegetable kingdom; whether it is located in the skin, as in scabies, in the muscles, as in trichinosis, in the lymphatics, as in erysipelas, in the solid viscera, as in amebic abscess of the liver, in the intestine, as in relapsing fever, the introduction and multiplication of the living infectious agent constitute infection." (Sternberg.)

The distinction as understood between infectious and contagious disease relates principally to the nature and method of introduction of the disease germ in different affections, and has its importance in the matter of treatment, the kind of isolation required, and other preventive measures. The passage of contagion in diseases of the first class may be, and ordinarily is, through the air to susceptible individuals coming within its reach; the less volatile germs of diseases of the second general variety are themselves more tenacious of life, find lodgment in clothing, may infect houses, are liable to be taken in the ingesta, and require different treatment and management in exclusion. What has come to light in the study of bacteriology has not only largely increased our knowledge of the means of preventive medicine, but has made this appear a legitimate field for work under the control and with the support of State and municipal government, and has given direction therefor.

Already in several of the States, in many of the larger cities, and in the Canadian Provinces, as well as in countries and cities abroad, bacteriologic laboratories are established and supported by National and State health authorities. In some instances examinations for diagnosis, analyses of water and food products, and other works are done for State and local health departments in college and private laboratories. The importance of this work in the domain of State preventive medicine is now generally understood and appreciated. As exceptional, however, to this, and seemingly below the general average of intelligence

and good judgment in the country, is the fact that a certain class of persons, even in the present year, has tried to secure the passage of a national law for the District of Columbia, forbidding the use of guinea-pigs, rabbits, rats, mice, and a few other animals, in the practical study of the great art of preventive medicine. These mistaken would-be-philanthropists have little knowledge of the saving of human life and the prevention of disease and suffering already accomplished by discoveries in science due to these means of study.

THE PROVINCE OF BACTERIA.

Not all bacteria are necessarily pathogenic when existing within the body, but are controlled in their action by circumstances and conditions. Besides, they may not be wholly without advantage to the natural world. Scientists have shown in various ways the importance of bacteria in their relation to the existence of organic life on the earth. Placing man at the head of the scale of living beings and the unicellular organisms known as bacteria at the foot, Dr. Sternberg gives the general view as follows: "The relations of these microbes to the lord of creation are more important and complex than those which exist between man and any other group of living organisms. "In the absence of bacteria or of some other organisms to perform their function, the continuous existence of man would be impossible; for it is due to their activity in decomposition of animal and vegetable substances that organic material, stored up as a result of the vital activities of higher plants and animals, is returned to the soil and atmosphere after the death of these. Without such a provision of nature, organic life would long since have come to a standstill from the storing up of those essential elements which go to make up the structure of animal and vegetable tissues. But as a result of the decomposition of such tissues after death, through the agency of bacteria, these elements are released from the complex combinations in which they exist, and again become available for the nutrition of living plants and animals."

Various kinds of bacteria have an important part in the etiology of disease. Certain disease germs are necessarily pathogenic in themselves, and others may become so when lodged in a soil the condition of which is suitable for their development.

CONCERNING IMMUNITY.

Among the problems made prominent, and concerning which much has appeared in aid of their solution, is that concerning susceptibility on the one hand, and power of resistance on the other, to the encroachment of disease in the various organs of the body. In this, marked difference in different animals and man have been found; and the practical advantages of knowledge gained by experiments in this direction appear in the more accurate and complete knowledge afforded in the choice and application of protective means.

Immunity to disease infection may be natural to a body under certain conditions, or it may be induced by artificial means. The first is shown in cases in which disease germs are known to remain harmless in the body, while vigorous and healthy action is maintained in the tissues, but when this is reduced they at once begin their work of destruction. The micrococcus of croupous pneumonia has been found in the salivary secretions in quite a percentage of healthy individuals examined. During the prevalence of diphtheria

in a household, diphtheria bacilli have been found in the mouths of individuals who presented no evidence of diphtheria infection. Here the germs were in no way taken into the tissues, and were without even local effect. Diphtheria is especially a disease of childhood, for the reason that the tissues of the child's body are more susceptible to its infection than are adults. When the disease is fatal to the younger members of the family, the older members often escape with a slight throat infection which shows the specific germ, but which works its own cure by the production of its own antitoxin in the infected parts, and fails to result in a general disease. It is found, however, that fatal infection may be given from these otherwise unimportant cases, hence the necessity of careful isolation in these cases as well as in others, as a means of preventing extension of the disease. This is further illustrated in a case reported by Rosenbach² and mentioned by Senn, in which an apparently healthy mother gave birth to a child suffering, when born, from acute osteomyelitis. The infection here must have been transmitted to the fetus from the blood of the mother, whose body was itself immune to the action of germs of this disease.

Pathogenic bacteria affect the animal organisms in two principal ways: First, by depriving the cells of different animal tissues of oxygen and nitrogen and appropriating the same to themselves in their multiplication and growth; and second, by infecting the solids and fluids of the body by certain toxic substances which they secrete. Aside from the toxic substances secreted by bacteria, which are in a greater or less degree injurious to the tissues and may cause death, there are other substances resulting from the action of bacteria, which affect the tissues of the animal so as to prevent further infection of the same disease germ. In this fact appears the explanation of immunity, as it results from an attack of infectious disease thus acquired. The length of time that it holds in the body varies greatly in different diseases and in different animals, races, climates and conditions. It must be said, however, that the exact nature of the change or changes which take place in the body resulting from the introduction of disease virus, the action of which causes immunity to a future attack of the specific disease, has been a matter of question. Some have considered it to be the neutralization of certain substances existing in the tissues or fluids of the body, which are necessary to the development of the specific bacteria; others, that the action of the disease germ in an attack is productive of certain substances which, remaining in the system, prevent the further action of the particular germ. Other theories have obtained, but what is now known seems to be only, that by an attack of the disease, the tissues are in some way rendered wholly or in a great measure unsuitable soil for the future development of the specific germ. As expressed by Prof. F. F. Wesbrook, bacteriologist to the Minnesota State Board of Health: "We must admit that no one factor observed in the production or acquirement of immunity explains all the phenomena of the process. The blood or tissues of an immune animal will kill off either in test-tubes or *in vivo* only a certain number of microbes (to which the animal is immunized), after which the others (if above a certain number be introduced) will grow, since it is neither exhaustion of the food material nor increase alone of the metabolic products of the bac-

¹ Immunity and Serum Therapy, p. 12.

² Surgical Bacteriology, p. 21.

teria themselves, but an anti- (bacterial or toxic) substance which is capable of being overcome by a large dose of microbes."

Among the more important diseases affecting either man or the lower animals, or both, in which different forms of bacteria are found to exist either as specific causes or as necessary concomitants of disease actions, are acute pneumonia, tuberculosis, glanders, leprosy, anthrax, actinomycosis, variola, typhoid fever, yellow fever, cholera, diphtheria, tetanus, such affections as have been called plague, venereal diseases and other diseases generally of minor importance, including the contagious diseases of childhood. There is now a history of discoveries made and facts demonstrated concerning the character and modes of action of the different specific bacteria in disease. These discoveries for the most part have been the result of continued labor on the part of scientists, and have not come from fortunate accident. The practical advantages which have resulted or may result from these advances vary in extent and importance in different cases, but all afford evidence of the coming of a more complete knowledge in pathology, looking to more complete means of cure and prevention.

Concerning the present practical advantage of a knowledge of bacteriologic pathology, Dr. Sternberg remarks, in the preface of his late work³: "At the present moment we are in possession of experimental facts and data which open to us a vista of possibilities in specific treatment unsuspected a year or two ago." He then speaks of the pathogenic action of specific bacteria in the etiology of disease, and of the methods of experimental work employed in researches leading to the discoveries. In this study appears the explanation of what is meant by natural and acquired immunity, and of the latter, the ways and means of its production.

In the latter part of the eighteenth century, Jenner, seemingly by accident, discovered the means of immunizing the body to the infection of variola by the introduction of the germ of the milder disease, vaccinia. This discovery marked the beginning of an epoch in the history of medicine. It remained, however, for men of science in the latter part of the nineteenth century to discover the physiologic character of artificially induced immunity, and this, not by accident nor by outward observations alone, but by continued experimental study in biology, done in the light of modern anatomy, physiology and chemistry.

A brief mention of the history of a few late discoveries and the procedures in securing immunity to the infection of two or three of the diseases mentioned, will serve to illustrate the character of work in this important department of preventive medicine.

MEANS AND METHODS.

There are three principal directions in which the means of preventive medicine have been employed especially against the advance of communicable diseases: 1. In reducing the source of infection propagation to the minimum by means of sanitation, shown in the sanitary care of houses and house surroundings, the purity of the air of dwellings, schoolrooms and places of public gathering, by correct ventilation; the improvements in sewerage and house plumbing, under authoritative inspection and direction; the examination of food products and water-supply, and concerning the condition of public conveyances, the method

of disposing of the dead, etc. 2. In preventing the passing of contagion, by authoritative isolation of the infected. 3. By securing immunity to disease in the individual, when necessary, by artificial means. In each of these departments of work a practical knowledge of bacteriology, of the character, behavior and the possible management and destruction of disease germs, has come to have an important place.

1. In the first department of sanitary work here noticed, the knowledge of what constitutes a means of propagation—the germs of various diseases—such as filth on persons and in and around dwellings, decaying animal and vegetable matter, and the want of pure air and sunlight in basements, as aids in the production and growth of the bacillus of diphtheria and other infectious diseases, has laid the foundation and led to the enactment of laws authorizing and compelling sanitary inspection, with provisions for correcting and improving unsanitary conditions by State and municipal authority. Besides this, it is seen that the authoritative cleansing of private houses, public places, persons, animals and things has an important result for good in the educational influence which necessarily attends the same.

2. The importance of effort in the above mentioned second department of sanitary protection from disease, is seen in what now exists in international, State and municipal quarantine, with the amount of governmental expenditures for this purpose. The financial view is that the loss of life and property incidental to the existence of pestilential disease is greater to the State than the cost of defense.

3. What is now known and practiced by way of rendering the body incapable of contracting infectious disease merits a somewhat extended notice. Only a brief mention may be attempted here.

Animals may be rendered immune to specific infection by the injection of the attenuated virus of the particular disease germ. The discovery of this is given to Pasteur, who in 1880 experimented with fowls in the disease known as "chicken cholera." Having learned that this disease is due to a specific germ which could be cultivated in artificial media, the further discovery was made, that the virulence of the germ became diminished in the process of culture. It was accidentally noticed that certain fowls injected with old cultures did not die, and later were immune to fresh cultures which killed other chickens. The attenuation in the old cultures is supposed to be due to exposure to oxygen. The germs having been thus reduced in their pathogenic power, when injected into healthy fowls were found to produce a comparatively mild attack of the disease, which resulted in immunity to further infection.

Pneumonia.—Another illustration of the method of securing immunity is seen in the treatment of pneumonia in man. A bit of history may have place here. The pathogenic germ of this acute disease of the lungs was discovered by Surgeon-General George M. Sternberg in 1880. He is said to have first detected it in his own saliva. Not then being aware of its connection with pneumonia, he named it "micrococcus Pasteuri." Pasteur discovered the same thing independently in the saliva of a child suffering from rabies in December, 1880. It was described by Sternberg in a paper to the Pathological Society of Philadelphia, in April, 1885, and was published on July 1 of that year in the *American Journal of Medical Science*. Here is a case, the like of which has not been uncom-

³ Written in 1892.

mon, where a question arises as to the priority of discovery because of the nearness of the dates of the first public announcement. The German scientist, Fraenkel, published his discovery of the same micrococcus only thirteen days after the published announcement of Sternberg; and the germ has been called "Fraenkel's diplococcus of pneumonia;" this for the reason that he appeared to have first shown the relation of the microbe to this acute disease of the lungs. Dr. Sternberg gives credit not only to Fraenkel, but to Weichselbaum, Netter, Gameleia and other experimenters, for discoveries and improvements in bringing the knowledge obtained into practical use.⁴

It has been determined by experiment on susceptible animals, that immunity for pneumonia may be had by inoculation with an attenuated culture of the disease germ; and that the completeness and duration of immunity thus produced bear relation to the degree of immunity caused by a natural attack of the disease.

For details in the work of preparation of cultures and their use in treatment, reference is made to the practical works of bacteriologists now available.

Anthrax.—Another disease that may be noticed in this connection is anthrax. This disease occurs epidemically among herbivorous animals—sheep, oxen and others—and may be communicated to man. A historic summary is given in the practical work of Muir and Ritchie,⁵ in which is shown the discoveries made in the bacteriology of the disease, which have led to a knowledge of its pathology and rational management. First, in 1840, Pollender discovered rod-shaped bodies in the blood of anthrax animals; in 1863 Davaine named these bodies the bacillus anthracis. Koch, in 1876, made his first contribution to bacteriology, in which he confirmed the view that the bodies were bacteria, and made discoveries concerning the formation of spores on these bacilli, their multiplication by division both in animal tissues and in cultures outside the body, and, by inoculating animals with them, produced the disease artificially. Pasteur disagreed with Koch in some minor points, but in the main confirmed his observations. The existence of spores on this bacillus, and the fact that these may be cast off and distributed outside the body, and that the vitality of these germs may remain for considerable time in spite of desiccation and great changes in temperature, appear as an explanation of the natural spread of the disease. The author here quoted sums up concerning the advantage of the study of this particular disease germ as follows: "Not only is bacillus anthracis easy of growth and recognition, but in its growth illustrates many of the general morphologic characters of the whole group of bacilli, and is therefore of the greatest use to the student. Further, its behavior when inoculated in animals illustrates many of the points raised in connection with such difficult questions as the general pathogenic effects of bacteria, immunity, etc. Hence an enormous amount of work has been done in investigating it in all its aspects.

Glanders.—This well-known infectious disease, which principally affects the horse, is sometimes found in other animals, and may be communicated to man. It is generally believed that in glanders no means of communicating the infection exists, other than that of direct contact with the affected parts of the diseased animal, or with some substance

on which the infection has been lodged. The following illustrative case has been published: A young lady while traveling fondled and kissed a small dog belonging to a traveling companion. The dog had been noticed to sneeze frequently. After arriving at her destination the young lady was first affected with a redness of the tip of the nose, which did not yield to any remedy; then the nose became inflamed and painful, and began to secrete mucus, and a diagnosis of influenza was made. But the case grew worse, ulceration occurred and increased, and the microscope revealed a case of glanders. In this case the disease germ may have passed from a horse to the dog and then to the human being. The practical lesson concerning prevention is obvious.

In Diagnosis.—Not the least important use of various cultures of disease germs is that in diagnosis. The use of mallein, tuberculin and cultures of the typhoid bacillus in diagnosing the affections of which these substances are the attenuated germs, may serve to illustrate. Mallein is a fluid obtained from cultures of the glanders bacillus. This was first discovered by Schultz and Loeffler in 1882. Schultz, as late as 1894, first taught concerning the difference in reaction in horses which were or were not infected when inoculated with mallein. It was found that after the inoculation in glandered animals there occurs a decided rise in temperature, and around the point of inoculation is seen a circumscribed swelling. In animals free from glanders, less febrile reaction occurs upon inoculation.

The similar use of tuberculin in the diagnosis of tuberculosis both in animals and man has recently received attention. Analogous to this is the serum (Widal) test for typhoid fever. What has come to light as a result of study in this disease is mentioned by Pepper and Stengle⁶ as the most important contribution to the progress of internal medicine during the year. Concerning its value, it is remarked by these authors, that in the year investigators in every part of the world have tested its value, and with remarkable consonance declare it a diagnostic method of the very greatest importance. Dissenting voices have been heard, but these for the most part represent no considerable authority or following.

The diseases and methods of investigation and treatment here mentioned are given only as illustrations of the few for the many. What shall be the changes and developments in means, methods and results, remains to be determined in the future. Great progress has been made, but not without labor and self-sacrifice. Besides, it is true that no advancement in medicine and science has ever been made without opposition. Objectors and critics, both within and without the medical profession, have never been lacking. Intelligent criticism is advantageous and helpful in the discovery of truth; but objection which comes from ignorance, and for this reason is more assertive, may be troublesome for a time, but in the end is harmless. The intelligent student of science has no time to spare with such would-be-instructionists. His work concerns great and important means of progress, the present outlook concerning which gives promise of most valuable results.

THALASSIC SUBMERSION A MEANS FOR DISPOSAL OF OUR DEAD.

Presented to the Section on State Medicine, at the Forty-ninth Annual Meeting of the American Medical Association, held at Denver, Colo., June, 7-10, 1898.

BY D. LICHTY, M.D.

ROCKFORD, ILL.

The question most intimately following a *useful* existence here is a *harmless* absence after we are through. It is evident that some suggestion for the disposal of our dead, other than earth-burial or cremation, is needed, from the unsanitary character of the former and the natural repulsiveness of the latter.

To show that ocean burial is practical, sanitary, and will meet most of the requirements of sentiment and religion, and *all* those of sanitation, will be the endeavor of this argument. That the beautiful fealty of genealogy and consanguinity and the sacred associations of religion are factors to be considered in this as well as any other method for the disposal of the dead is recognized; but above and beyond these is the unpurchaseable boon of health and its attendant uses and beauty.

Every expedient that human thought could devise has been resorted to in all times past to conceal the human dead and escape their disagreeable, decaying presence and evade their naturally dreaded and noxious effluvia. The nomad's village was removed to fresher and more remote territory; the ancestral cave was promptly deserted and relinquished to the grim destroyer; the rare and desiccating air of the plains did well preserve the body until disintegrated and distributed to the sands and dust; birds and beasts of prey were invited to devour the softer tissues while the bones bleached in the sun and the mists. Chemistry has been invoked to offer an element that would preserve our form or else dissolve it quickly away; and modern electricity has been asked to envelop the loved ones in impermeable garbs of metal to preserve their cherished form and substance. Aquation or sea-burial, except in accidental death *at sea*, was only practical when navigation was so primitive that the hardiest mariner dared not go beyond the shallows or out of sight of his native land, and when bathymetry and geodesy of the ocean were unknown. The embalmers, from the Egyptians to the present, exhausted every resource of their art, then and now, to prevent the decay of the body; but Rameses' and Cleopatra's crumbling and repulsive features, held together with spiced pitch and rags, as seen in modern metropolitan museums, attest its grewsome failure.

All these have failed to satisfy the longings of devotion to our dead, or meet the present rigid sanitary requirements of our rapidly multiplying and dying population, and we seem to have still nothing left but to "inhume the natives in their native plains."

Earth-burial remains an unsatisfactory and unsanitary presence as well as relic. Incineration continues repulsive to all the finer feelings of nature, and we seek relief from all these in the truly *sanitary*, beautifully sentimental, and forever efficient disposal of our dead in the depth and vastness of the abyssal area of old ocean—illimitable and itself symbolic of the infinite in time and space—bride of the sun and vassal of the moon! "Nothing in Nature renders back to man the full and instant sympathy which is accorded by the mighty seas," who thus repose mildly in the generous grandeur of their glorious power.

Sentiment must have a place in this presentation, and in this every department of this subject can have a diversion and division as remote as *mythology*, as exact as *history* and *science*, and as generous as poetry aided by the imagination can plan, from Charon with the obolus, to pay passage, to Tennyson's "Crossing the Bar;" from "Jordan's Stormy Banks" to "Canaau's Happy Shores."

As we emerge from the eras of superstition and shallow thought, and realize that the organic individual is but a transient here, and that disintegration and resolution of the body into its primitive elements is but an arc in the circle of perpetuation: that care for the living, hope for the future and memory for the dead is our aim and object, so does it become forcibly apparent through every channel of study that the now well-acknowledged bane of earth-burial must somewhere, somehow, cease. The catacombs everywhere, instead of being monuments of skilled subearth engineering, are rather persistent evidences of a civilization so remote and crude that, without implements of excavation, they could only follow the sand strata and rock seams in their meanderings toward "points of least resistance" for repositories for their dead. An afterthought, with the then generally entertained idea of immortality of the material body, led to the attempts at decoration and barbarous body-ornamentation which the dry sand chambers and corridors favored by desiccating the bodies, absorbing the gases and preserving the then sacred and esthetic attempts at color ornamentation for the amusement of modern sightseers.

The deception that proximity to graveyards is harmless can not longer be maintained by corporations who own them, or municipalities that are supposed to control them. The study of bacteriology and the toxins, their secretions and their persistent life in all conditions; the penetrability of their gases to remote distances through pervious qualities and strata of soil; their escape and ascent into the atmosphere, all impress the danger of such acres (though sacredly and sentimentally named) on chosen picturesque hillsides, near ravines draining the water-courses, or inclining to wells from which the inhabitants of villages and cities derive their water-supplies and inhale the poison-charged air.

Every aggregation of population is confronted with this menace. London has its finest cemetery—Kensal Green—of 18 acres, containing 70,000 recent bodies, an equivalent of 3-1/5 bodies to the space allotted an ordinary grave. Paris has its Pere la Chaise, equally crowded; in 1871 the communists made their last stand amid its tombs and 900 fell in its defense and were buried where they fell, in two long trenches, their bodies mingled with quick-lime to hasten their dissolution. Other cities are struggling with this problem, owing to limit and contiguity of territory; building tombs above the earth; leasing the ground for brief periods only, and employing the chemistry of absorbents and deodorants and destructive acids to hasten disintegration, tossing the resultant dust to the garbage pile and fertilizing field.

A perusal of the daily lay papers furnishes a surfeit of ghastly recitals of graveyard desecration, of resurrection and demolition, of skeletons ruthlessly thrown about by workmen's pick and shovel within, or adjoining, hamlet or city, to make way for cable or conduit of commerce, or deep foundation for towering tenement. The category of horrors associated with our

crude plan of earth inhumation and attempted body concealment, despite all precautions, is neither in harmony with wholesome sentiment, economy nor in any sense approximate modern sanitary requirements. Every other phase of economics has advanced along progressive lines; ancient and modern plagues have been stopped; pain has been robbed of its terrors; time and distance have been annihilated; but a suitable and sanitary repository for our dead has not yet been secured. The "abyssal province" of the ocean, embracing 140,000,000 square miles, more than three times that of the earth's surface, and one hundred times that of the available area of earth, unfolds her limitless and aseptic bosom to envelop us; no actual bounds of length, breadth, height, or depth circumscribe her receptive capacity; the diversion of her shore lines are insignificant when compared with her area, and her perturbations are only on the surface; her deeper strata are scarcely moved in ages.

The wave

Unbroken in its tranquil aspect sleeps
Serenely as Beauty in her sunless grave;
Nor moves a tide, unless its silent flow
Be through the graves and coral halls below.

Ocean cables lie secure in their beds and swerve not though pulsating with war's weighty messages or love's tender tidings.

The antiseptic chlorin solution of the seas is as stable as air; dissipation and augmentation by affluents are compensatory and preserve a constancy of specific gravity. Its temperature at 400 to 1000 fathoms, in all latitudes in all seasons, day and night, is unvarying and on the verge of freezing. Decomposition, putrescence—the dread of the surviving and the bane of the air and the earth—do not take place in ocean burial.

Imagination naturally revolts at the inexorable chemistry of decay that must take place in vault and subsoil burial; putrescence at the bottom of the sea is unknown; ferruginous matter does not find its way beyond the extreme three-hundred-mile shore line, but here and beyond all is carpeted with pelagic deposits, crumbling remains of the inhabitants of the upper strata, feeding bathybius and the diatom, medusæ and the crinoidea. Here disintegration will some time, sooner or later, proceed by an alchemy unknown to the present denizens of the earth. Ships go down along the paths of commerce, but deep-sea dredgings find no relic of the myriads that have sunk in her tracks; iron ships soon corrode and wooden ships are easily comminuted; ocean cables enveloped in heavy vulcanite remain long untarnished; gold, glass and heavy porcelain survive; all else soon disintegrates and sleeps forever—a slow accretion to the solid diameter of the globe. Over all is constantly descending through the waters like a snow-cloud, showers of microscopic shells, product of the higher strata. At these depths there are no real or chimerical "sea monsters;" animal life diminishes in the sea as the depths become extreme. The investigations of Professor Agassiz in the Pacific Ocean show conclusively that there are but few living forms below a depth of 1800 or 2000 feet; only minute and peculiarly formed and encrusted animal life can survive at this pressure.

Thus a body deposited on its "watery plains" or in its ferny cliffs, and marked on chart by degrees and minutes of latitude and longitude would be as definitely located, as if sepulchered in mausoleums of granite on mountain side or village vale amid earth's shifting scenes.

Compare the area of the stable and abyssal seas with that of the earth, and its limitless boundaries invite undisturbed repose; subtract from the earth's surface lakes, mountains, marshes, rivers and inaccessible territory, tillable lands for the sustenance of the living, and it leaves but a handful of earth for the myriads that already slumber in its bosom, or the unknown millions that shall live and die hereafter.

That change must come in the matter of the disposal of the dead is certain; that cremation during a third of a century of education and argument is far from acceptance and adoption is patent. Fire is the natural foe and dread of man, incineration can not by any force or play of the imagination surround itself with as pleasing sentiment as ocean burial can. Resolution by fire is repulsive to all our nature; no one can come near a natural-gas or fuel-oil furnace, much less look into its glowing, roaring caverns without being terrorized in its presence, and no persuasion could urge one to remain while the body of their friend dissolved and disappeared in its fury, or even while preparation was going on therefor. Besides this, it is too expensive for general adoption, and its hygiene and utility are still doubtful. The expense of a single Sieman's retort in working order, without necessary buildings, is approximately \$2000. Sir Henry Thompson's process is more expensive, and Polle's but little less, in the experiments thus far made use of. By Polle's method two hours were required to reduce a body. Sieman's process required fifty-five minutes after the retorts had been brought to their required degree of heat. At the cremation of the body of the late Frances Willard the body was left in the retort *all night* that the "ashes" might cool. This, in part, realizes the expense and impracticability of cremation when it should be applied beyond the experimental stage, and for those few only who, through persistent indoctrination, signified their willingness before death to submit to this form of dissolution. Witnesses to a cremation do not usually become advocates of the process. I asked a mother, three months after she had complied with her son's request to be cremated, and she had carried his body across three States to fulfil the promise, what she thought of it? She quickly dropped her head and an expression of horror was on her face when she looked up to ask me not to refer to it. The complaint of crematory managers is that parties do not even return for the "ashes," and their vaults are overcrowded.

Admitting that the expense of transportation to a suitable wharf and a distant crematory are equal, the further consummation by ocean burial would be far less expensive and less repulsive than cremation. The bidding adieu at the "Gatesajar" on a cleanly wharf, as a clean boat sailed away over the waters, would be far less trying and have a pleasanter memory than such a leave-taking at the sooty door of a crematory, or to hear the final rumble of the clods on the coffin-lid six feet in the cold ground below. Further, the presence of a large crematory plant of say ten or twenty retorts would soon prove a nuisance in a neighborhood, and its location be as difficult to secure as that of a powder factory.

Consider an aggregation of population like New York and vicinity, numbering nearly five millions, and its death-rate of 15 per 1000 or 75,000 deaths per annum—over two thousand per day to be consumed; who could say that retorts, flues and stacks would not

soon be clogged? Imperfect combustion would result and noxious vapors therefrom fill the surrounding atmosphere. What a battery of furnaces and retorts this would require. No pleasing memories could cluster around such a place. No wonder that even material Germany shrinks from adopting the experiment, and of its dense population gave only a little over two hundred bodies to the experiment last year.

This subject has been presented to marines, travelers, landmen; to Christian and infidel; and while with all, naturally, death is dreaded and the first suggestion of disappearance by submersion or by any means from the ken of men, is startling and dreaded; at a renewal of the subject after a time for thoughtful reflection they would invariably, as between earth-burial, cremation or ocean submersion favor a thalassic grave. As to *incineration* and urn and mantel preservation, fifty years after its revival from barbarous methods, aided by all the modern methods of propagating and advancing an innovation, its *non-acceptance attests its failure*. The proverbial dread of fire does not apply to water; submersion and disappearance beneath the wave can not have associated with it the horror of disappearance by fire. Watery submersion as *immersion* is both a pleasant and a sacred symbol of burial and a new birth or *resurrection* to a large body of Christian believers to whom ocean burial should be a sure surcease from dreaded earth-burial or incineration. A large percentage of suicides choose drowning rather than any other form of extinguishment, and prove their preference for a watery grave to plunging into a fiery retort at rolling-mills or Bessemer converters.

There can be no very loving sentiment that may cluster around a bowlful of incinerated, gluey bones called "ashes" and summoning to memory a beloved face and form of which they were wont to form a part. Thoughts of the positive putrefaction of the loved ones, or how "the small cold worm fretteth the enshrouded form," can not be realized; or how beneath the coffin lid and its "six feet two" of weight of cold clods, rest can not be more sweet, and the form more secure than to be buried in the deep,

Where the sea flower spreads its leaves of blue;
That never are wet with falling dew.

Religion and sentiment combine to explain why there is no more ready and favorable movement in favor of *burning* the dead.

Immortality that is to be had only by preserving a handful of bones or mourning over a mound of clay in God's Acre is indeed nothing much to be coveted. "We must be found in the register of God, not in the record of man." The memory of the child or parent can not be less profound for the ancestral body that sleeps somewhere in fatherland, across the broader waters, the site of which they can never hope again to visit. Are the 150,000 brave sons, brothers and husbands of our late Civil War, who sleep in *unknown graves* less cherished than those who sleep in "God's Acre" beneath the graven cenotaph? The white-capped emerald ripples in our national cemeteries marking the "unknown" indicate just as specifically *where* sleeps a hero and loved one as if they were buried beneath the green of Saragossa or the billows of the Atlantic.

We would not be retrograding either in sentiment or sanitation if our seaboard population were not so

dense, if we could revive the solitary, stately customs of the Viking chief, whose glory in defeat by death and in departure was to float outward to sea with the tide, reclining, surrounded by his trophies, in his crude but gorgeous craft until he was lost in the majesty of the sea, and sank to rest. The Columbia River Indians buried their dead by setting them adrift in their canoes with a lighted taper in the bow and watched the light and form go out on the broad sea and down together. Thus we are not advocating a custom that is without the sanction of precedent, or one that would conflict with the finer sensibilities of the surviving friends of those who at first *voluntarily* selected this method of burial, as has been done in cremation in the past.

It would seem that when ocean-burial is rightly studied, when the abyssal area is considered, the aseptic fluid that will envelop the form, the quiet that rests in ocean's depths,

When winds were raging over the upper ocean.
And billows wild contend with angry roar,
'Tis said far down beneath the wild commotion
That peaceful stillness reigneth evermore.

Far, far beneath, the tempest dieth,
And silver waves glide ever peacefully,
And no rude storm, how fierce soe'er it dieth,
Disturbs the Sabbath of that deeper sea.

Comparing the accessibility for all the seaboard area and the economy with other methods of final disposal of the dead, municipalities or may be corporations, would agree to add to the "white-winged fleets of commerce," and the "white squadron of war," the pearly palaces of peace, that would at stated intervals, near enough together to meet the requirements of the district's mortality, sail away with their sacred cargo to deposit it on the watery plains of the abyssal seas, when with Byron we would say:

Ours are the tears though few sincerely shed
When Ocean shrouds and sepulchers our dead.

Such steamers should be especially fitted for their work; they should have complete refrigerating apparatus and chambers fitted to receive all the bodies to be carried; these chambers could also be hermetically sealed as "bulkheads," or salt-water compartments, for the conveyance of contagious disease cases; they should be under the supervision and espionage of the municipal or State board of health. The wharves should be selected for their accessibility; should be capacious and scrupulously clean; fitting enclosure should secure the sacredness of the area, and within or adjoining might be a small, neat chapel. To those who still cherished the exclusiveness of the caste of wealth, rank or family—if death recognized such division—an area might be set aside in the abyssal field by the Geodetic Bureau, and they could be transported in their own or friend's private yachts, with such selected company as they chose, to share the sacred rite and private grief at the watery grave, where

The free waves kissed her with their cold blue lips
And then put her to sleep;
She has a sand pillow and a water sheet,
And never turns her head or knows 'tis morning.

The caskets or containers might be wicker-wrought as has been suggested for earth-burial, though fastened on a heavy iron or stone base; they might have fenestrated or latticed sides; or ornamental open-work to admit water and favor deep submersion: a suitable weight could be enclosed in or near the foot

of the coffin; if desired this might be of any heavy non-corrosive material, with which might be a graven or moulded number or merited motto, corresponding to a record kept in the family or State archives for the information of future antiquarians, should islands some time rise "unusherred from the seas"; where no provision had been made, a heavy concrete of water-lime might fill the lower interspaces and insure descent and submersion. If volunteers were not offered, the "Potter's Field" might surely spare its inmates for the early experimental stage and no breach of sentiment could arise to offend the fastidious.

That bodies would rise again from the formation of gases, as they do in fresh water, is not to be anticipated, from the fact that the lowered temperature and aseptic medium of submersion would both prevent and lessen further formation of gases. It is of record that during the earthquake at Lisbon in 1775, sixty thousand people sank into the sea at once and not one of the dead bodies ever floated to the surface; the water there *now* is only six hundred feet deep, whatever it was at the time of the cataclysm.

That funeral obsequies and ostentation are becoming more and more a burden is an economic fact from which many would escape did not the thralldom of conventionalism prevent. Church funerals are becoming less frequent; the gorgeous hearse, the solemn, nodding plumes and the slow and stately tread of somber comparisoned horses is giving way to the hurry trolley that ends at the gates to God's Acre. The money that is expended for the obelisk and the slab had better provide an endowment and a bed in a hospital for the unfortunate sick, crippled, or defective living. The fund that builds a mausoleum for the dead had better build a school or hospital; and the green cemetery-field that is polluted with decay, could in truth be made "God's Acre," when it was given up for park purposes in which could be beautiful *memorial* plats and avenues, fountains, restful grottoes, inscribed settees, chapels with capacious corridors, with limited spaces assigned or purchased, on which might be inscribed in brief the record and memorium of the dead; libraries and art galleries might award or sell similar spaces.

Thus there would be no territorial encroachment in hamlet or city, and the forsaken and haunted cemetery would become a place of recreation, retrospection and education for the living. Old Ocean would never become crowded, earth would be freer, water would be better, air purer. Life and health—the greatest boons of the Giver—would be strengthened and lengthened, and no harm have been done the dead.

SOME EXPERIMENTS ON THE VALUE OF CARBID OF CALCIUM IN THE TREATMENT OF CANCER.

Demonstrated to the Chicago Medical Society, Nov. 2, 1898.

BY EMIL RIES, M.D.

PROFESSOR OF GYNECOLOGY POST-GRADUATE MEDICAL SCHOOL,
CHICAGO.

In the JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION, July 2, 1898, an article appeared entitled "A Note on the Treatment of Carcinoma of the Uterus," by J. H. Etheridge, A.M., M.D., Professor, etc. At the start the author states that the idea of curing cancer by means of remedial agents has never found lodgment in his mind, while the improvement in the

condition of several cases of uterine cancer under the treatment described in the article seems to him worthy of record. Then follows a review of the opinions of various authors on the pathology of cancer. Next a description is given of the agent used in the treatment of the cases reported—the carbide of calcium—and the product of dissociation of carbide of calcium with water—the acetylene gas—is dwelt upon at some length, and the question of its toxicity discussed. The author then reports that in 1896 he first saw reference made to the carbide of calcium in the treatment of uterine cancer in some medical journal, which reported that some German physician used it in treating cancer of the uterus, and the author disclaims all pretense to originality in its use. He has forgotten the name of the German physician, and I have been unable to find his article or a report of it in any German publication now accessible to me. Now follows a description of the treatment as carried out in the cases reported. It consists in first curetting under anesthesia, then cauterization with the Paquelin cautery, irrigation with very hot water if necessary. After all this, the carbide of calcium is placed into the cavity thus created and the remaining space is packed firmly with iodoform gauze. The use of the carbide is repeated every three days. The results of the cases treated in this way are then reported, whereof more later.

The conclusions arrived at are the following: As to the *modus medendi* of the carbide of calcium the author has no opinion. Bacteriologic experiments were made with the carbide and with the acetylene gas with absolutely negative results. In a few cases an erysipelatous redness of the sound mucous membrane seemed to follow the use of the carbide, which would suggest that it resulted from an escharotic action of the acetylene gas. Now comes the, to me, incomprehensible statement: "Whether the acetylene gas destroys the cancer cell by annihilative action or by chemically changing it remains to be seen." And the article closes with the words: "One thing seems to be certain, and that is that the carbide of calcium at least postpones death and makes carcinoma patients vastly more comfortable while they do live than any treatment known to the writer."

So far this article. With the pathology of the author I am not concerned tonight any farther than to mention merely that as long as carcinoma is not proven to be a bacterial disease experiments on bacteria with carbide or with acetylene gas are, to say the least, premature in this connection. The rest of the article however, aroused my interest and after having given it the attention which the subject and the position of the author so fully deserve, I am forced to the statement that I disagree with him and believe myself able to make you disagree with him in practically every principal item of his article.

To specify I shall try to prove:

1. That the acetylene has no escharotic action.
2. That the *modus medendi* of the carbide of calcium is simple and easily understood.
3. That the author has utterly and absolutely failed to prove that carbide of calcium postpones death.
4. That the carbide does not make cancer patients more comfortable than any other treatment, even if we consider only those known to the writer or those which must be known to him.
5. That the carbide of calcium treatment not only is not superior to other methods of treatment of inoper-

able cancer but exposes the patient to some quite unnecessary dangers.

In order to prove these five points we have to look both at the chemic and the clinical sides of the question. To begin with the chemic part, I shall produce here a quantity of acetylene gas by dropping carbide of calcium into a test-tube with water, and I will expose one of my mucous membranes—my conjunctiva—to it. The effect is *nil* and remains *nil*, if I continue the exposure indefinitely. The same experience has been made by the authors who exposed various animals to more or less pure streams of the gas for considerable length of time—several hours—(see Rosemann *Arch. f. exp. Pathol.* 1895). A number of other experiments with the gas injected under the skin or into the circulatory system prove that the absorption of large quantities is an entirely indifferent affair.

To prove that I am dealing here with acetylene gas, I will light it and you see it burn. Even without lighting it, we notice one thing which is important and is entirely omitted from the article mentioned, viz., the production of heat during the dissociation of the carbide. This development of heat I can demonstrate best by dropping small quantities of water on the carbide. You see the water almost instantly turns into steam. In other words you can, by adding water in small quantities to the carbide, produce the temperature of boiling water. The same conditions prevail exactly in the cancerous cavity of the uterus, where the serum gains access to the carbide by slowly oozing out of the wounded organ. If you take the vessel in which you make this experiment in your hand you will feel that it becomes hot, and if you continue you will prefer not to hold it any longer in your hand. If however you throw the carbide into a larger quantity of water, the heat is much less noticeable, and you can place your hand in the water without noticing any escharotic effect from the acetylene gas developing all around your hand.

In order to get some idea how a patient would feel under this treatment, and in order to find out how high the temperature would rise on trying the dissociation of the carbide on the surface of the body, I place some carbide on my hand without water. No effect. The minute quantities of moisture adherent to the surface of the body are not sufficient to produce dissociation. So on September 4, I tried adding a drop of water on my left upper arm, where you still see the scar and the pigmentation. Immediately I noticed a smarting pain which stopped soon after all the water had been used up in the dissociation. When I then removed the remnants of the carbide I expected to find a simple burn, an erythema or a blister. But I found something else. Instead of the expected blister I found a soft grayish slough surrounded by a red area. That was evidently not due to the heat but to something else, and this something is more important, though it is entirely omitted from consideration in the article mentioned.

Let us look for a moment at the chemic formula which represents the changes discussed here. We have:

Now CaO is an old acquaintance—quicklime—and what effect quicklime has on human tissues is known to the bricklayer as well as to the fake cancer specialist who advertises "cancer cured without knife." The

medical profession generally has abandoned the use of this substance, be it in its original condition or in the various disguises in which it was put up, as Vienna paste, etc. Most deservedly so, because quicklime forms a soft slough; because it does not limit its own action by producing a firm impermeable layer, as for instance the strong acids do. Therefore its effect is uncertain as to the depth of the slough produced. The same reason exists why the carbide of calcium can not be used for checking an active hemorrhage. I sacrificed two dogs before I had gained the experience that the heat produced by the dissociation of the carbide with the blood from the cut surface of the lung or of the liver was a less prominent feature than the softness of the slough which allowed the blood to well out again and again. In one case the dog succumbed to the hemorrhage from the lung, and in the other case the hemorrhage from the cut surface of the liver had to be checked by the actual cautery to save the dog from immediate death. Let us keep this in mind when we turn to the clinical side of the question.

To sum up the chemic part of the question: carbide of calcium brought in contact with water is dissociated under the production of considerable heat into the indifferent acetylene and into quicklime, which in its turn immediately becomes slaked lime. This process again is accompanied by a lively development of heat. The therapeutic effect of carbide of calcium brought in contact with any moist surface of the body is nothing but the well-known effect of quicklime—a remedy long abandoned and for good reasons.

But—and now we turn to the clinical side—how about the clinical facts? Do they not prove the treatment superior to any other? By no means gentlemen: The first case reported has been under observation from December, 1896, till May, 1898. The patient first noticed her symptoms six months before she came for treatment, say June, 1896. She has, therefore, been living with her cancer 23 months. Case 2 has had symptoms since February, 1897. The last report of her condition is dated May, 1898. Total 15 months.

Do these two cases prove that carbide of calcium postpones death? I fail to see that such a conclusion would be warranted, for the very simple reason that a great many cases of cancer of the uterus live that long and much longer without any treatment or after other palliative methods of treatment have been followed. I have picked out at random from my small collection of inaugural theses of German universities a pamphlet by Ditges, which reports a number of cases of cancer of the uterus which refused treatment or were treated with the curette or the Paquelin alone, and the time of death of which was ascertained from the official records kept by the authorities. This little book shows numerous cases where death did not occur until three or more years after the first symptoms developed. And this is not the only book which contains such records. A. Martin, for instance (*Pathol. und Ther. d. Frauenkr.*, 1895), records a case which lived five years without radical operation. In fact, every surgeon who has had some experience with cancer of the uterus is most willing to acknowledge that the prognosis as to the duration of the disease is extremely uncertain. The two cases in the article mentioned do not present any extraordinary length of life after the first symptoms, and therefore do not prove that carbide of calcium postponed death.

The article fails to prove that the carbide of calcium

treatment makes cancer patients more comfortable than any other treatment. First, it is a very common experience that after incomplete operations or after simple curettement or use of Paquelin cautery with various powders or ichthyol or chlorid of zinc treatment the patients are very comfortable for months, many so much so that they consider themselves cured. It must be remarkably bad luck on the side of the author of the article mentioned, if he has never seen such results after treatment with the curette and cautery. I refer to this treatment specially, because it certainly is one known to the author of the paper mentioned as is shown by his report of the treatment of those two cases which included the curette and cautery. And this is the second reason why I can not accept his paper as conclusive evidence in favor of the carbid of calcium.

The cases described have not been treated with the carbid exclusively, but in addition to it with methods which, in the hands of other surgeons, have given fully as good results as those described in the article mentioned. If we combine treatments in this way, conclusions from the results can not be relied upon in a scientific discussion. A third point is to be mentioned—the age of the patients. One is 69 years old, the other 53. It is by no means uncommon to find a very slow progress of cancer in women of that age. A fourth point and a very important one is that, according to the author's own report, both cases give very palpable evidence of a progress of the disease. Case 1 reports May, 1898, that she was "having an occasional bloody grumous discharge from the vagina coming with a sort of gush as though the pent up fluid—about a dram in amount—was suddenly released, that it had an odor like old fish, not like cancer, that it had been going on at intervals for a few days, for about a month." It takes only a very limited experience with cancer to understand what is going on here. The cauterized cervix has contracted, the uterine canal has been strictured, carcinoma is spreading, and the discharge from it accumulates above the stricture. No report of a bimanual examination is furnished. The report that the vagina shows no solution of continuity does not prove anything as to the condition higher up. It is a very old experience that cancer of the cervix frequently spreads upward and outward, leaving vagina and external os almost intact. In Case 2, the treatment was begun July 30, 1897. In February, 1898, patient became ill with a chill and pelvic pains. On the eleventh day an abscess suddenly discharged through the small opening in the vault of the vagina. What has happened? Either a pyometra or an extrauterine abscess has formed, as is seen so frequently in the course of carcinomatous disease, and the report that the vagina shows no solution of continuity affords no certainty whatever as to the spreading of the disease, especially as again no bimanual examination is recorded. Are these the superior results which form the pride of the article? In the first case hemorrhage and odor are present; in the second a septic condition somewhere around the uterus. So the carbid of calcium has not prevented either of them.

We have to say a few words concerning the dangers lurking in the carbid. There is first the danger of the slough extending to an undesirable depth, producing perforations which make the patient's condition worse than before. Secondly, it is possible that some of the quicklime gets to points where it is not

wanted and produces unnecessary injuries—a danger which is not very great in the hands of a manipulator of any experience. Thirdly, it must be mentioned that acetylene gas mixed with air in a pretty wide range of proportions is highly explosive and that copper or brass instruments, as sounds, etc., must not be used in this treatment, because copper forms an explosive combination with the acetylene gas.

To conclude, I wish to state why I read this paper here; why I make these demonstrations. It is a constantly recurring complaint of the gynecologists that the cases of cancer come into their hands when it is too late, when no operation, be it ever so extensive, can save them. It is also a constantly recurring complaint that the cases which are sent for operation have been under internal or topical medication for a number of weeks or months before the medical adviser comes to see that his treatment availeth naught, and that not until then he hurries the patient off to the surgeon—who then gets the blame if the recurrence follows his radical endeavors all too rapidly. Now I fear, and from the questions which have been put to me from the ranks of the general practitioners, I have good reason to fear that a report like the one in the July number of the JOURNAL, which I have tried to refute here, is only too apt to create new confusion, to lead to more tinkering on the cancerous cervix, and to jeopardize numbers of lives which could be saved if they were subjected to the only proper treatment we know of at present—the extensive radical operation. It is not the fault of the author of the article in the July number if the opinion has gained ground that the carbid of calcium promises to effect a radical cure. He disclaims that expressly. Nevertheless, I know that this opinion is spreading among practitioners.

As to the use of quicklime in the shape of the carbid of calcium in cases of inoperable cancer, centuries of surgical experience have given a verdict which does not encourage new experimentation. The carbid of calcium will henceforth assume its place among the worthless and dangerous remedies for carcinoma.

100 State Street.

SOME CAUSES OF WRY-NECK.

Presented to the Section on Neurology and Medical Jurisprudence at the Forty-ninth Annual Meeting of the American Medical Association, held at Denver, Colo., June 7-10, 1898.

BY C. M. HOBBY, M.D.

IOWA CITY, IOWA.

The object of this paper is to report facts, leaving the consideration of their bearing upon the condition commonly known as wry-neck, for the future. The writer does not believe that disturbances of the nervous equilibrium, which in a few isolated cases are relieved by successful treatment of peripheral irritation, are to be considered as the result of that special irritation. As in epilepsy we occasionally have apparent cure, by correction of the refraction, or by some form of treatment of so-called muscular imbalance, as well as by operating for phimosis, and as the same measures have frequently been followed by the cessation of chorea, so in the following instances torticollis has recovered, after the removal of ocular conditions, apparently little more likely to have exerted a causative influence in its production. That there is nothing original in this suggestion, is shown by a remark in Vol. vii, p. 557, of the "International Encyclopedia of Surgery," edited by Ashhurst. "Young, Lovett

and others have shown that there is sometimes a curious relation between ocular defects and torticollis." (Referring to Trans. Amer. Orthopedic Association, 1891, Vol. i, p. 46; Vol. ii, p. 230.) I have not access to these reports.

The first instance in which I was able eventually to predicate ocular influence in the cause, occurred in 1893, in a boy of 15, whose deformity had existed for several years, and in whom the muscular contraction was apparently structural. There was no spasmodic element; the abnormal position was constant, the head drawn well toward the right shoulder. Finding that any forcible correction was attended with diplopia, I was led to the discovery that paresis of the left inferior rectus existed, and a subsequent tenotomy of the superior rectus led to a gradual but eventually complete recovery from torticollis.

The second case, P. N., male, age 12, was seen in June, 1896, and gave a history of impaired vision, and asthenopic symptoms existing for more than a year preceding. Three weeks before examination, he had severe headaches, followed by nausea and vomiting, coincidentally with diplopia. As he got better the head became twisted and drawn toward the right shoulder. Examination showed 8 degrees of esophoria, each eye, also a low grade of hypermetropic astigmatism with squint apparent at times. In this case correction of the refraction and "ocular gymnastics" brought about recovery in two months.

DISCUSSION.

Dr. D. R. BROWER of Chicago—I would like to ask Dr. Hobby one or two questions about his wry-neck cases in regard to this matter of a possible reflex origin in connection with these several conditions that have been mentioned here. I would like to know something about the neurotic condition of these cases that Dr. Hobby has described, and in which his treatment seems to have been so remarkably successful. It is my impression that in the care of these and of similar cases, the condition of every peripheral end-organ should, if possible, be ascertained, and the errors, if any be found, corrected; but I wish to emphasize what Dr. Norbury has said, and what my friend, Dr. Gradle, has also emphasized in his paper: that after all it is the constitutional condition that demands our most careful attention. End-organs that are out of order must be put in order. I care not whether it is a defect in the eye or in the nose, wherever there is a peripheral end-organ out of order, the derangement of which can be corrected, it should be corrected. But I think there are very few cases of wry-neck, of headache, or any other condition of the nervous system similar in kind, that are altogether and entirely due to some such disturbance of the peripheral nervous system as has been so ably described in those two interesting and valuable papers. I desire to emphasize the necessity of finding out the constitutional state; and herein lies the difficulty in the treatment of these cases of headache.

Dr. C. C. HERSMAN of Pittsburgh—With reference to Dr. Hobby's paper, the author has had better success in treating wry-necks than I have. Sometimes these wry-necks will continue for months, however greatly improved. Occasionally we may make a mistake in the diagnosis of wry-neck. A patient of mine, a child of three years, I diagnosed as suffering from meningitis. Another physician however, a week later diagnosed the condition as wry-neck. I was not much relieved by the other doctor's opinion. The trouble continued until about the thirteenth day, when the child was very much better, but I still told her mother not to be hopeful. On the fourteenth day the child took suddenly worse, and a very severe meningitis developed, followed by death.

Dr. HOBBY—I especially disclaim the belief that peripheral irritation was the fundamental cause in the great majority of those cases which were relieved by the removal of the peripheral irritation, such as the occasional relief of epilepsy by treatment of ocular conditions and matters of that kind, the operation of phimosis, etc. We used to be taught concerning the immediate cause and the remote cause; and we used to think that sometimes the peripheral irritation, added to the constitutional condition, would produce the given difficulty. It was as exceptional instances that I reported these two cases

of wry-neck in which the ocular cause seems to have been extreme. I do not believe that many others of these cases will be relieved in the same manner. I simply wished to bring the attention of the Section to the fact that wry-neck was due to ocular diseases in some cases.

DO WE DRAIN TOO FREQUENTLY IN PELVIC SURGERY?

Presented to the Section on Obstetrics and Diseases of Women at the Forty-ninth Annual Meeting of the American Medical Association, held at Denver, Colo., June 7-10, 1898.

BY W. H. HUMISTON, M.D.

Associate Professor Gynecology in the Medical Department of Western Reserve University; Gynecologist-in-Chief St. Vincent's Charity Hospital; Consulting Gynecologist City Hospital.
CLEVELAND, OHIO.

Since the publication of a few cases in the February, 1898, number of the *Medical Council*, I have had a series of pus cases, some of which were of such a serious nature, and of such a virulent infection, that a most thorough test of non-drainage of these cases has been made, and the results in all have been satisfactory and beyond my expectation.

I am fully alive to the fact that there must be a certain (small) percentage of our cases in which death can not be averted whatever the technique may be, but on the other hand I am assured from the careful study of my own, and the cases of other surgeons, during the past five years, that the mortality in pelvic surgery has been kept too high, *partly* by the indiscriminate use of some form of drainage. Lawson Tait says, "That there is an inevitable mortality in abdominal section I think is certain." He bases this "inevitable mortality" rate between 3.5 and 5.5 per cent. upon a series of 1350 consecutive operations.

For years I had relied upon the glass drain as one of the most necessary adjuncts to my technique in pelvic surgery. In all cases where there have been extensive adhesions separated, and large areas of oozing peritoneal surfaces left, I have been most careful to thoroughly wash the peritoneal cavity free from all debris, and held it especially important to use a glass drainage-tube for twenty-four or forty-eight hours. However, my records show that during the past four years only one case outside of my own private hospital was drained in this manner.

It was not that the cases were of a less serious nature, but they were not drained because I feared a subsequent infection of the peritoneum through unskillful handling and dressing of the tube. In such cases, then, it was a choosing of the lesser evil when I closed the belly without supplying an artificial drain. I have reached this confidence in the closing of the abdomen without drainage through a long series of cases.

A widow, aged 23 years, had one child, and had had one miscarriage. Tubercular tendencies inherited from both father and mother. Contracted gonorrhea one year previous to her admittance in City Hospital. Operation December 21, 1894. Double pyosalpinx with general pelvic adhesions. Uterus held in retroversion by inflammatory products. Pelvic organs and intestines were covered by miliary bodies, closely resembling, in macroscopic appearance, tubercular areas (pathologist failed to report his examination). Considerable oozing. The peritoneal cavity was carefully cleaned and dried and the belly was closed without drainage. This is only one example of a number of early cases in which I felt compelled, on account of unfavorable surroundings and conditions, to close

the peritoneal cavity without the use of a drain, a measure inconsistent with my teaching and usual practice of that time. The uniformly happy result in each successive undrained case in the 1894 series was very unexpected.

My mortality rate has been decreased almost *pari passu* with the declination of the rate of drained cases: In 1894, 71 per cent. drained, 14 per cent. mortality; in 1895, 36 per cent. drained, 7 per cent. mortality; in 1896, 33 per cent. drained, 6 per cent. mortality; in 1897, 4.33 per cent. drained, 4.66 per cent. mortality. And so far in 1898 I have drained no case, and the mortality rate is as low as 3 per cent.; in fact, to be exact, 2.8 per cent.

During the year of 1896 the glass tube was supplemented by gauze in almost every case in which the glass was used. In these cases the dressings would not be disturbed until the expiration of the first twenty-four hours. The tube would then be removed, and the gauze would remain undisturbed for three or more days. This was merely an expedient to avoid frequent dressings and so lessen the danger of infection. During the past year, however, I not only discarded the glass tube, but also any former conception of the values of all drains in the ordinary cases of pelvic surgery, so that the 4.5 per cent. of cases which are counted as drained during 1897, really only represent the cases in which gauze was used—either in the form of the Mikulicz apron, or of simple strips—for the purpose of controlling such oozings which I feared would be too copious for the peritoneum to care for. I feel that this is yet too high a percentage of open wounds, and confidently hope to almost minimize the number during this present year.

In those cases in which I know the peritoneal cavity is contaminated, I thoroughly wash out the pelvis with a saline solution, using it for the purpose of dilution of infection rather than with any idea of antiseptic worth, and close the wound, leaving within the peritoneal cavity as much of a fresh salt solution as it will contain. This radical change of opinion in the management of my cases has been slowly brought about by close observation and study of my clinical cases. I have been reassured, however, in my position by the reports of different bacteriologic researches, such as that from Dr. John Clark of Johns Hopkins Hospital, wherein particularly the dangers of drainage are well defined. This report was published in the *American Journal of Obstetrics*, in April and May, 1897, and should be carefully considered by every abdominal surgeon. I append a few illustrative cases:

GENERAL AND PELVIC PERITONITIS.

Suspension of the uterus was performed upon Mrs. S. in December, 1895, in Philadelphia, and in January, 1896, a second operation was performed for a ventral hernia.

In February, 1897, when she had been seven months pregnant, she began with severe labor pains. The doctor in attendance removed per force, a dead and macerated child. She developed thereafter a very severe form of puerperal fever.

On May 11, 1897, when I first saw her, the exudate extended midway to the umbilicus. No areas of softening could be found. She was very much reduced in general health.

On July 12 she was operated upon at the City Hospital. Throughout the upper two-thirds of the old scar were found very dense omental adhesions; and about the lower angle, the anterior uterine wall, near the fundus, was adherent over a space of nearly three inches square. The uterus was exceedingly large and very dense. The pelvic organs were matted together with inflammatory exudate. The uterus and its appendages were removed and an effort was made to cover as much surface as was possible with the remnants of peritoneum left in the pelvis. The belly was closed, and the patient passed through to a rapid convalescence.

RUPTURED TUBAL PREGNANCY.

On July, 27, 1897, at my hospital, Mrs. H. was operated upon. The right half of the pelvis was completely shut off from the general peritoneal cavity by adhesions between omentum, intestines and belly walls. This formed a pocket which was filled with partially organized blood and lymph, and in the bottom was found a large hematoma of the ovary and the ruptured tube. The left appendage was normal. Adhesions were carefully separated, the vessels were tied, the pelvic cavity was thoroughly cleaned, and the belly was closed. She left the hospital on the twenty-fifth day in good local and general condition.

GONORRHEAL PYOSALPINX.

At Akron City Hospital, on July 31, 1897, I operated upon a case for Dr. Cleaver. Cases had had recurring attacks of pelvic peritonitis until she was very much reduced. The pelvic organs were closely matted together by adhesions of both old and recent date. Bleeding and also general oozing was free. Both tubes contained pus, and the ovaries showed evidences of chronic inflammation. After the pelvic cavity was wiped dry and clean by strips of plain gauze, three pints of salt solution were poured into the belly, and the wound was closed. Dr. Cleaver reported that her progress was rapid and favorable.

Mrs. K. conceived in June, 1897, miscarried in October, and was admitted to the City Hospital in the first week in December. A diagnosis of double pyosalpinx was made, and the operation was performed on December 11, 1897. During an examination by several of my students, just immediately preceding the operation, the left tube was ruptured. On opening the belly it was found that the pus had escaped into the pelvic cavity, but had been hindered from contaminating the general peritoneum by a wall of adhesions. The appendages were removed, and the pelvis was cleaned by mopping the cavity out with gauze strips and irrigating with saline solution. Just before closing the belly $2\frac{1}{2}$ quarts of salt solution were poured into the peritoneal cavity. From cover-slips a staphylococcus was found, together with what was thought to be the gonococcus. A culture in bouillon was obtained, but unfortunately no differentiation was made.

In this case the temperature after operation never reached a point above 101°, and after the tenth day was noted as normal both at morning and evening. She was dismissed on Jan. 3, 1898—twenty-three days after operation.

AN OVARIAN CYSTOMA (SUPPURATING).

Mrs. P., a widow, aged 50 years, has borne two children, the youngest of whom is 17 years of age. Her first menstrual period occurred when she was 18 years old. They recurred regularly and lasted usually five days; they were unattended by pain, and the quantity of the flow was small.

Since the birth of her last child, however, she has suffered severely with dysmenorrhea, and her general condition has been much impaired. The labor was long and difficult, and shortly after the puerperium, she noticed a prolapse of the uterus which eventually became complete. Her family history is good, and there is nothing in her general previous history which bears upon the case. On May 20, 1895, she first noticed an enlargement of the belly in the left iliac region. It continued to increase, making unusual gains at irregular intervals, until the latter part of March, 1897, when the tumor steadily and rapidly increased. About this time she began to have repeated attacks of chills followed by fever, great tenderness throughout the entire abdomen, and emaciation with loss of strength. The diagnosis of an abdominal tumor was made a year ago, but the patient refused then to permit an operation to be made. I first saw the case on June 13, 1897, in consultation. We found the patient in great distress because of the interference with the respiration and the heart's action. Her temperature was 103, and pulse 130. She was anemic and greatly emaciated. Edema of the lower extremities extended above the knees. The tumor completely filled the abdominal cavity, pressing the xiphoid outward at a right angle to the sternum and widely flaring the lower ribs. The circumference of the belly at the umbilicus was forty-five inches, from the xiphoid to the symphysis pubis twenty-three inches, and from the free end of the twelfth rib to the middle of Poupart's ligament of the opposite side thirty and one-half inches. A complete prolapse of the uterus was found. Her general condition was very poor. Her temperature when she was admitted to my hospital, June 16, 1897, was 100 degrees, pulse 130 and very weak. Examination of the urine showed a very small daily quantity, with a large amount of albumin, renal cells, and granular casts. The case was not a promising one for radical operative measures. She had reached such a point in her suffering that she was willing to submit to an operation, preferring death to an existence accompanied by such extreme discomfort.

We operated after five days of preparation, in which laxative baths, restricted diet, drinking of hot water, and strychnin were used. On June, 13, through an incision in the linea alba, I tapped the cyst and removed its walls. Sixty-four pounds of fluid were drawn off. There were no adhesions to the anterior wall, nor to the small intestines. The posterior wall of the cyst was intimately adherent to the omentum. To both sides, but particularly the right side, the adhesions to the lateral abdominal walls were both dense and vascular. A great deal of organized lymph was found between the stomach and the apex of the cyst. All adhesions were broken, and immediately the bleeding points were ligated. It became necessary to remove the entire omentum. A great surface of the lower curvature of the stomach was adherent to the fundus of the cyst, and a mass of inflammatory exudate was removed between the cyst and the lower surface of the liver. The pedicle was three inches in length and about the size of the little finger. The patient's condition was very precarious. The pulsations in the radial arteries had ceased for a time, but quickly responded to the application of a large quantity of hot saline solution into the belly cavity. After thorough washing, four quarts of the normal physiologic salt solution, at a temperature of 114 degrees F., were left in the peritoneal cavity, and the incision was closed *without drainage*. The pulse steadily gained in strength and fulness, and became less rapid as the fluid was absorbed, and contrary to expectations there was no interruption to a very rapid convalescence. Her condition did not even warrant an attempt at suspension of the uterus. In truth, we made haste to get her off the table alive. She was dismissed in four and one half weeks from the day of operation. We found a prolapsed right kidney and an attempt to replace the prolapsed organs was made. Failure to reduce them was evidently caused by adhesive bands.

On September 18 the family physician reported that he found the patient working hard at the family washing. She had gained twenty-five pounds, and was free from all aches and pains, excepting at times a dragging in the region of the prolapsed liver. Microscopic examination of the mass bounded by the liver, stomach, and fundus of the cyst showed simply a mass of organized lymph, although macroscopic appearance was that of malignant degeneration. The weight of the tumor and its contents was seventy-two pounds, and the patient after its removal weighed not more than eighty-five pounds. The tumor was a simple glandular ovarian cyst with suppuration.

DOUBLE TUBO-OVARIAN ABSCESS (GONORRHEAL).

Miss A., aged 18 years, gave the usual history of gonorrhea and its sequelae. On March 8, 1898, with great difficulty I removed both uterine appendages—they were tubo-ovarian abscesses. The pelvis was roofed in by inflammatory exudate, and the appendages were deeply imbedded. In their removal pus was spilled. Much of it was caught on the gauze stripe with which I always protect the general peritoneal cavity, but the structures in the pelvis were thoroughly covered. The pelvis was irrigated with hot saline solution and the belly was closed with two quarts of salt solution remaining.

In the bacteriologic examination of the contents of the tubes and ovaries, a *viride* staphylococcus was found. A severe form of other pneumonia was first noticed eighteen hours after operation. Complete hepatization of the two lower lobes of the right lung followed. Barring this accident the convalescence was normal. The patient was dismissed in four weeks. Later she reported herself in good general health.

In conclusion I would again affirm the opinion that almost, if not every case of pelvic surgery requires no drainage. That even those cases in which there is a general infection (the cases which make up largely the totality of those designated by Tait as the "inevitables") can not be benefited by drainage.

Let us then recognize more fully both the expediency and the dangerous factors in the use of the drain, and so lower to a minimum the present high rate of mortality, that even the best of our operators yet attain.

THE IMPORTANCE OF THE STERILIZATION OF FOODS AND DRINKS BEFORE THEIR INGESTION.

Presented to the Section on State Medicine, at the Forty-ninth Annual Meeting of the American Medical Association, held at Denver, Colo., June 7-10, 1898.

BY AUGUSTUS P. CLARKE, A.M., M.D.

CAMBRIDGE, MASS.

In presenting this subject for consideration it has not been so much my aim to cover all the phases which the question involves as it has been to bring before the Section that portion of the theme on which I have some definite conclusions. All will admit the importance of bacteriology and will not fail to appreciate the wonderful results achieved.

Professor Virchow, in his address on "The Continuity of Life," before the general session of the Twelfth International Medical Congress at Moscow, spoke of the gradual progress that had been made by the use of the microscope, and said that its evolution had given rise to a new impulse in the march of medical science toward the development of biology. He attributed our indebtedness for the marvelous working of that instrument to Ehrenberg of Berlin. Prior to the achievements, the results of the study of Ehrenberg, as published in his "Über die Infusionsthierchen als vollkommene Organismen," all the ultimate aspects relating to the nature and character of the various histologic elements and bacterial agents were shrouded in the deepest mystery.

One of the most striking illustrations of disregard by the public of proper precautions that should have been taken for protection in the use of milk, which is subject to infection, occurred in Cambridge in the summer of 1896. Though typhoid fever is a disease that has been more or less endemic in the metropolitan district, the cases are usually sporadic, and in their manifestation are for the most part of the milder type. During the months of August, September, and October of 1896, an epidemic of that disease raged with unusual severity. For the month of July of that year the number of cases reported by the various physicians in practice was 19, the number in August was 84, in September 56, in October 43, in November 23, and in December 14. The number of cases reported for the six months immediately preceding was as follows: in June 4, in May 3, in April 0, in March 3, in February 3, and in January 3. The local board of health, aided by an agent of the State board, in endeavoring to ascertain the cause of increase in the number of cases that occurred, succeeded in tracing their appearance for the most part to families supplied with milk by one particular dealer. Careful inspection of the dairies did not reveal any irregularity in the conduct of the business. There was, however, evidence tending to show that a workman who had been indisposed with what seemed to be a mild attack of typhoid fever, had been allowed to wash the cans. The total number of deaths from typhoid fever in Cambridge during the year of 1896, omitting the non-residents, was 30, while the number in 1897 was only 11, a fraction over a third of the number in 1896. The number of cases of typhoid fever reported in 1897 was as follows: in January 5, in February 5, in March 1, in April 1, in May 7, in June 6, in July 5, in August 10, in September 15, in October 24, in November 12, and in December 14—making a total of 105 cases, or 150 cases less than in 1896.

In this connection there were some personal obser-

vations worthy of note. In a number of families no attacks of typhoid fever occurred, though the members of the families were free users of milk. For a long time I have endeavored to impress the importance of sterilization of milk before using it. In some few instances I have succeeded in bringing about a reform.

In one family of six persons the only one who suffered from an attack of typhoid was a lad of 16 years, who insisted upon taking cold and unsterilized milk. He was accustomed to indulge freely in the use of uncooked milk while the rest of the family, receiving the milk from the same source, though not using it until after it had been properly prepared, escaped altogether. In my own family during the year of the typhoid epidemic above referred to (1896), the milk supply was from the source ascribed as the cause of the increased number of cases, though none of the family suffered except the domestic, who preferred cold uncooked milk. She frequently drank a glassful at a place of retail, whose supply, it is said was obtained from the same dealer, as was that supplied to our own household. She suffered from clearly defined symptoms of typhoid. A son and a domestic of a physician not far from my residence were among those who during the epidemic partook of the milk before it was sterilized and were sufferers from typhoid. The milk was from the same milkman.

In 1894 eight cases occurred in rapid succession among persons taking milk from the same milkman. The trouble originated at a farm in Bedford whence some of the milk was brought. Some time previous to these attacks of typhoid, a number of cases occurred in which the trouble was traced to another dealer's milk. Milk is often an almost indispensable article of diet in the treatment of many forms of disease and in the after-treatment or management of surgical cases. For this reason I have frequently relied upon the advantages of a milk diet.

In 1893 the number of cases of typhoid reported in this city was 92, an increase of 12 from the previous year. Males seemed to have furnished the larger number (53). It may be, says the reporter, that in taking meals away from home more frequently than females they have exposed themselves to the danger of introducing into their systems the morbid germs. This statement as touching upon our duties as medical advisers should be regarded as most significant.

There can be now no question intelligently raised as to the infectious nature of typhoid fever. The agency of the bacillus of Eberth is undoubtedly the cause. Water for domestic purposes may become contaminated by the presence of typhoid germs, as was well illustrated in the outbreak which occurred in the Borough of Newport, Isle of Wight, in 1894, when some 436 cases out of a population of 10,512 were observed.

Some writers have regarded Pasteurization as sufficient for protection against micro-organisms. This method of proceeding is effected by subjecting liquids for about half an hour to a temperature of 160 degrees F. before their introduction into the system. Such a limited treatment will not always prove adequate for complete protection against the ingress of bacterial elements.

The temperature should be carried to the boiling point, and maintained there for some minutes lest the spores of many of the pathogenic organisms escape destruction. A convenient process of sterilizing

drinking water is found in the use of bromin. Ammonia will serve to neutralize this chemic agent. Schumburg uses 0.2 c.c. in a solution as follows: water, 100; bromin, 20; potassium bromid, 20, for each litre, and then neutralizes it with an equal amount of 9 per cent. ammonia.

Some waters require an increased amount of bromin to overcome the ammonia which it contains. I have tried this and have been pleased with the results, especially when it has been necessary to use water very freely in a case of prolonged illness and when objection is raised on the part of the patient to the use of boiled water. The taste is not disagreeable from the presence of the slight amount of bromin salts.

Mention of this formula is made in *THE JOURNAL*, vol. xxviii, page 655. Professor Vaughan, in his communication to the Congress of Demography, in London, 1891, stated substantially that milk had often been diluted with water containing germs of typhoid fever, and that the prevalence of the disease had been traced to milkmen's supply. The same author makes mention of 138 epidemics of typhoid fever, 50 tabulated by the late Mr. Ernest Hart of London, 88 collected by himself. All these outbreaks were due to a specific pollution of milk. Mr. Hart had made record of fifteen epidemics of scarlet fever, and Professor Vaughan had found data of 59 others, making a total of 74 epidemics that had occurred through the medium of contaminated milk. Reference again to Dr. Kennedy's paper read before the American Public Health Association, 1896, shows that of 138 epidemics of milk typhoid, 74 of scarlet fever and 28 of diphtheria—a total of 240 epidemics—187 have been noted by English writers and 31 have been described by American observers. The English and the Americans have been much behind the nations of the continent of Europe in the use of the means for protection against contaminated foods and milk. In the hotels and restaurants of Mexico I found that hot or boiled milk, either through custom or for sanitary purposes, was freely used. The freshly prepared tortillas and the hot tomares impregnated with pepper could be partaken of at any time with the least possible danger from infection.

The contraction of tuberculosis from milk supply is another subject that has engaged the attention of state authorities. The reaction to the test of tuberculin in cattle showing suspicious symptoms of the disease has proved most helpful to the government in taking measures against the use of contaminated meat and milk. Cases have been reported in which a cow, apparently in good condition, reacted to the test of tuberculin; and after being slaughtered showed evidence that one or more portions of the lungs were in an advanced state of tubercular degeneration. A cow that is well fed and housed and has had but little exercise may prove to be affected with tuberculosis without presenting any manifest symptoms of such disease.

In my own practice a number of interesting facts have been noted. Some years since, before the public authorities had become aroused to the possible dangers of milk and meat supply, a young man of good family history was taken ill with tuberculosis. He had been very fond of raw or fresh milk. Some few years after his marriage his symptoms became worse, from which he succumbed. The younger of his two children was the next victim. His wife

whose parents and ancestors on both sides were of good health and of long life, was the third to be attacked. In the same house and mingling with the same family, her brother's child was seized with a fatal attack of tubercular meningitis. The next patient was the mother of this last child (living in the same family). The ancestors of this last patient were noted for their unusual vigor and longevity. I should state that the older of the two young children of the father who died was not nursed by the mother, but was fed from the bottle. Until the child grew to a considerable size she continued the use of milk, and seemed to insist, as her grandmother said, upon her food being of a temperature that would almost scald any ordinary child to take. This desire on the part of the child, according to our present understanding was her salvation. Her growth was rapid and her physique became most excellent. The distinguished consultant called in at the time of the occurrence of the various cases, remarked that the contagionists would claim in these cases that they were the result of the communicability of infection, though he at that time, thought it best to wait until more facts were brought out before an expression of opinion should be made. Attacks of scarlet fever and diphtheria should be especially guarded against. Milk is no doubt often the medium for the transmission of the germs.

There are some well-recognized articles of food whose treatment should be most carefully studied. Everyone knows how frequently are seen bread, and other foods or eatables, that have been more or less exposed to dust laden with germs and to various forms of exhalations, sold to customers and consumed by them without the slightest regard being paid to the dangers incident to such contamination. All such articles should be subjected to the purifying action of heat at varying degrees of temperature and at intervals according to the length of their exposure, their susceptibility of becoming the vehicle for transmission of germs and the uncertainty of the sources from which they have been derived. This should be especially observed whenever a zymotic or contagious disease appears among children or occurs in a family of several persons.

The boards governing the public water-supply may be attentive to duty, they may use all reasonable means to guard against its pollution and may resort to the best methods for its filtration still this great commodity when thus treated will at times be far from innocuous, as the records of repeated epidemics have shown. The application of heat at 170 degrees, or at the boiling point for some minutes, until all germs or micro-organisms and their spores have been destroyed, will overcome the dangers from imbibing such waters and will preclude the necessity of having to resort to the use of spirituous liquors as a substitute.

Examination of facts in regard to the manner in which the meat-supply may be secured leads to the conclusion that all such articles of diet should be thoroughly sterilized before they should be ingested. (*Boston Med. and Surg. Jour.*, vol. cxxxviii, p. 282.) It is too much, says a writer, to expect that when only one or a little more of the thoracic lymph-glands of an animal which has been slaughtered for food has been found affected with disease, the entire portion of the meat should be thrown away. Disease, as it has often been shown, may be restricted to areas or foci

near the stomach, to a small part of the liver, or to a limited section of a lung; in such cases the inspectors may not condemn the meat as unfit for food. The question will no doubt be soon brought before some of the State governments for determining what should be the proper course to pursue in dealing with such cases. It has been reported that the flesh of at least one-half of the animals which have reacted to tuberculin has been found on postmortem to be affected only to a limited extent.

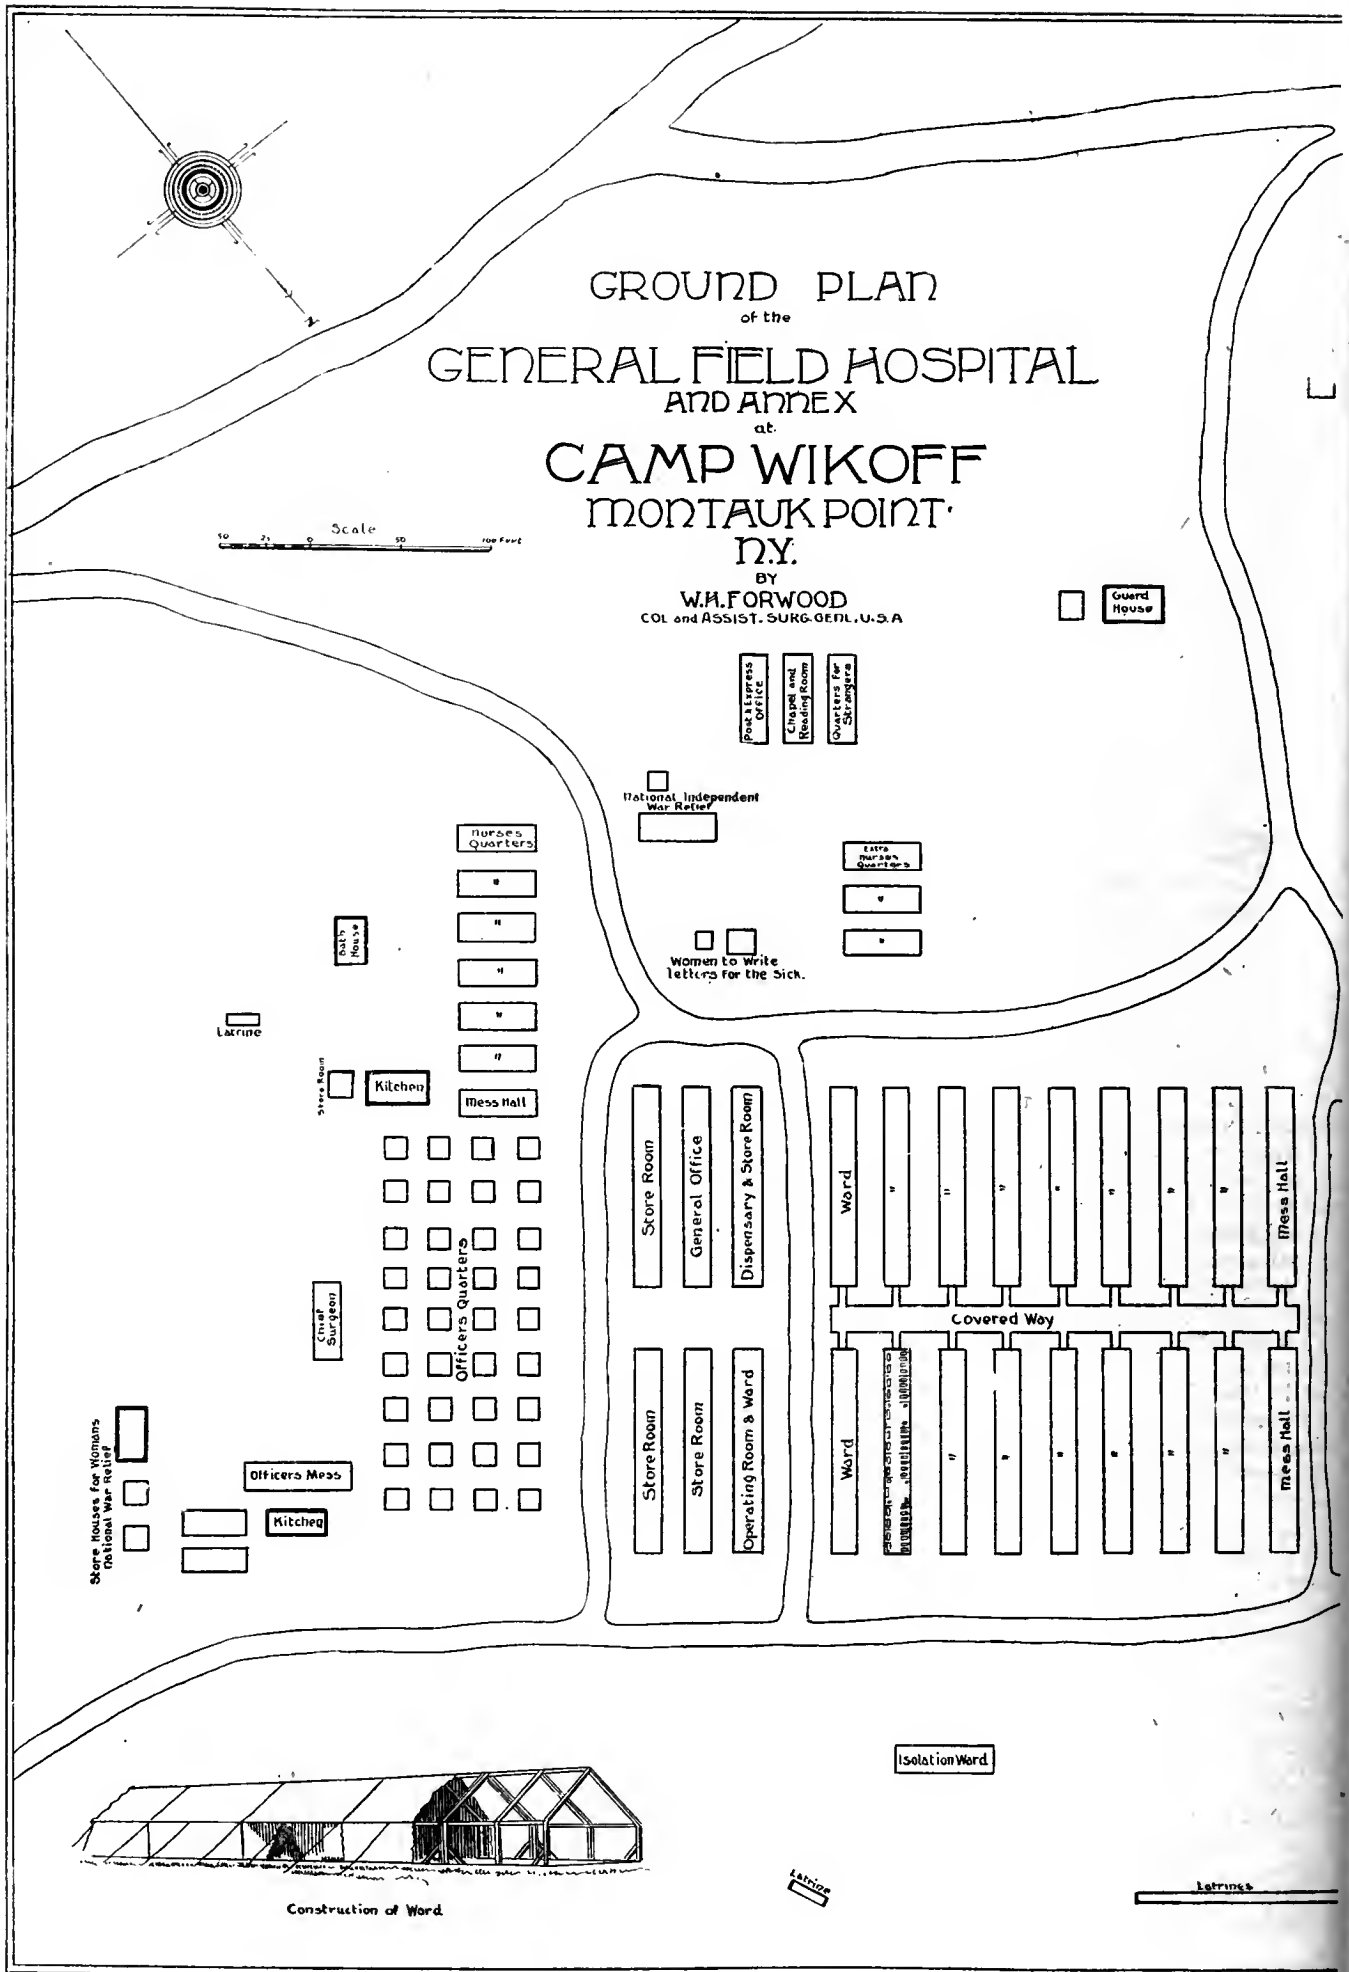

To enforce rigid inspection of animals and then to prevent the use of all meats as food when in any way affected, without regard to the extent of the disease would result in an unnecessary loss to a State and in an unwarranted waste to its inhabitants. Persons are not infrequently appointed as inspectors who have no practical knowledge of the duties of such a trust. If the races are to continue to be consumers of meat as heretofore the safest course for a family or person to pursue is to see to it that all meats, in whatever form they may be presented or from whatever source they may be delivered, are so sterilized as to destroy all bacilli or other micro-organisms.

THE SURGERY OF CAMP WIKOFF.

BY N. SENN, LIEUT.-COL. U. S. V.

CHIEF OF THE OPERATING STAFF WITH THE ARMY IN THE FIELD.

The great national Camp Wikoff has been made the recipient of the returning army of Cuba. Three months ago the invasion of Cuba was ordered. Our troops left the different camps in excellent condition and good cheer to meet the Spanish army in the neighboring island, fully informed and impressed with the events that awaited them. The army of invasion considered it a privilege to be called to the front to represent the military prowess and power of this country. The outside world had no conception of what our army could accomplish at such short notice in a distant tropical country. The authorities, and particularly the medical department, were fully aware of the fact that the invasion of Cuba meant more a battle with climate and disease than the weakened, sickly, half-starved Spanish forces. The invasion was planned on the spur of the moment, and the corps were rushed to the front with a haste that appeared all out of proportion to the conditions of things as they presented themselves at the seat of war. It was decided that our flag should float over the city of Santiago on the Fourth of July regardless of consequences. The army of invasion was packed on transports days before the final order was given to sail. Here was one of the many causes that impaired the health of our troops. The lack of harbor facilities on the coast of Cuba, where our army landed, made disembarkment and the landing of supplies exceedingly difficult. Most of the barges intended for this purpose were wrecked during the voyage, a serious loss which could not be remedied in time. Much suffering was caused by the lack of efficient landing and transportation facilities. Our troops were supplied with rations calculated for our climate, but not adapted for a tropical country. Our soldiers were exposed at once to malarial infection in all of the camps. Occupation of the buildings in which yellow fever had full sway for years, and the free intermingling of the filthy Cuban refugees and soldiers with our troops could not fail in starting and disseminating this disease among our soldiers soon after landing on Cuban soil. Typhoid fever, which prevailed in all of our large camps before the army sailed for Cuba, soon gained a firm foothold at the seat of war and did its share in increasing the mortality and in shattering the efficiency of the service. Amebic dysentery and diarrhea, the two greatest enemies of the Spanish army, thinned out our ranks and crowded our imperfectly

equipped hospitals. It was fortunate that the enemy yielded to our arms so early, and made it possible for our troops to return so soon to the invigorating climate of the North for proper care and speedy recuperation. Those who saw the different regiments leave our State and national camps would find it difficult to recognize and identify the soldiers of the Cuban campaign. The men left in excellent spirits. Most of them return as mere shadows of their former selves. The pale faces, the sunken eyes, the staggering gait and the emaciated forms show only too plainly the effects of climate and disease. Many of them are wrecks for life, others are candidates for a premature grave, and hundreds will require the most careful attention and treatment before they regain the vigor they lost in Cuba. The surgery of Camp Wikoff represents cases and pathologic conditions which we would expect to occur in men suffering from the effects of disease, exposure and the debilitating effects of a tropical climate. Our work has consisted

iron frame and top. Sterilized dressings, gauze sponges, ligatures, etc., are kept in sterilized towels in readiness for use at any moment. The shelves and tables are covered with white rubber cloth, which is kept scrupulously clean. The instruments, after sterilization, are kept in trays containing a 2 per cent. solution of carbolic acid. Saline and antiseptic solutions are kept ready for use in four-gallon bottles. All surgical paraphernalia not in use are covered by clean white sheets. The second tent, open at the sides for free ventilation and coolness, is used for the office of the surgeon in charge. It is supplied with a field desk, table and chairs. Section No. 3 is the preparation room. The instruments are kept here under lock

MAJOR HEITZMANN, SURGEON U.S.A.

largely in the treatment of abscesses and operations for fistulae and hemorrhoids. I was ordered to Camp Wikoff on my return from Porto Rico, and reported for duty August 22. The field operating tent and surgical wards, already in construction, were completed in two days. I have been assisted in my surgical work by Major Charles Adams, U. S. V., and Acting Assistant-Surgeon Henry Greenleaf. The Sisters of Charity have charge of the surgical wards, and two of them make the necessary preparations for operation and assist in the operating tent.

SURGICAL HOSPITAL.

The surgical hospital at Camp Wikoff is a part of the general hospital. It consists of nine wall tents, placed end-to-end and supported by a substantial wooden frame and floored throughout, constituting a pavilion of 126 x 14 feet in extent. The front tent, No. 1, facing southeast, boarded at the sides, with a broad table shelf on either hand, is used as an operating tent. It is equipped with a regulation operating table,

MAJOR BROWER, SURGEON U.S.A., IN HIS OFFICE, GENERAL HOSPITAL, CAMP WIKOFF.

and key. Two sterilizers, basins, buckets, pitchers and a table constitute the equipment of this room. A glass irrigator and a number of fountain syringes furnish the facilities for irrigation. A field operating case, a Paquelin cautery, a full set of dental forceps, a complete set of urethral instruments, a case of eye and ear instruments and aspirator have furnished all the instruments required. The instruments are sterilized by boiling, the dressings by dry heat.

Hand disinfection consists in scrubbing for at least five minutes in hot water and potash soap, washing in absolute alcohol followed by prolonged immersion in a 1-1000 solution of bichlorid. Just before the operation is commenced the hands are washed once more in alcohol. The field of operation is disinfected in the same manner as the hands. Section 5 answers the

purpose of a pantry and kitchen for special diet. From here the distribution of food takes place as it is received from the main kitchen of the hospital. Between the supply tent and the pantry is an open passage-way four feet wide, through which the patients and nurses enter and leave the hospital. The four tents remaining are used for wards, having a capacity of 32 beds. This hospital in the course of a few days was filled, when ward A, adjacent, occupied by medical cases, was evacuated to make room for surgical cases. The present arrangements affords room for seventy-five surgical patients. At the present time, September 10, every bed is occupied. The six Sisters of Charity in charge are assisted by three orderlies from the Hospital corps. Patients are prepared for operations with proper antiseptic precautions, and no pains are spared to give them the benefit of modern surgical methods in every detail, during their stay in the hospital. The nursing and care of the sick are faultless, and the diet is not only ample in quantity and quality, but often luxurious, far exceeding what is served on the table of the officers' mess tent. The patients much reduced in flesh and strength by fever or suppurative affections, are furnished with a liberal supply of stimulants including champagne and port wine. With very few exceptions indeed, prompt improvement has followed the operative interventions, more especially in the cases of large phlegmonous and ischio-rectal abscesses. It is my intention in writing this paper to give the profession a general idea of the surgical work done in Camp Wikoff since I took charge of this branch of the hospital work August 22. Nothing had been done up to that time in caring for the surgical cases. The hospital was overcrowded, and the available physicians were extremely busy in looking after the welfare and accommodation of the fever patients. In two days I had the surgical ward in a condition to receive patients, and on the third day the first operations were performed. At first a pocket case did sole duty in the operating room. The hospital outfit and supplies were picked up here and there, and in a few days we were ready to begin systematic, efficient work. Many of the patients were so weak and anemic that the administration of an anesthetic was deemed dangerous. In such cases the patients were given strychnia subcutaneously and a liberal dose of whisky by the mouth. Patients considerably enfeebled by disease were given ether in preference to chloroform. Chloroform by the drop method was the anesthetic of choice in all cases where the general conditions of the patient did not contraindicate its use. Operations were performed during the forenoon, beginning at 9 o'clock.

TOOTHACHE.

Of the organs frequently affected among the returning soldiers were the teeth. Patients suffering from carious aching teeth were numerous. In most instances they presented evidences of serious malnutrition following disease and exposure; suppurative alveolitis was less frequent. Infection of many oral cavities showed that teeth had been sadly neglected during the campaign. In Cuba and Porto Rico I saw occasionally a soldier with a tooth brush under the hat band, but I have reason to believe that most of the tooth brushes were either left at home or thrown away on the march, as unnecessary articles of the limited toilet outfit. I did all I could in the way of conservative dentistry by cleaning out cavities and packing with cotton saturated with carbolic acid, but in the majority of cases the patients returned and insisted on having the painful tooth extracted. Tooth extraction was a conspicuous and grateful part of the surgery of Camp Wikoff. Hardly a day passed without two or three such operations. A very complete set of tooth forceps furnished by the government did good service in relieving the victims of toothache of their agonizing suffering. Much has been said in favor of attaching a dentist to each regiment to look after the teeth of the men, and the observations made in Camp Wikoff tend to support the propriety

of such a much-needed addition to the medical service. It is interesting to know that among these patients there was not a single officer, undoubtedly because the officers were more particular in the care of their teeth than the privates.

HERNIA.

The number of hernias that presented themselves in Camp Wikoff astonished us all. In every case the statements of the patients were to the effect that the hernia appeared since the enlistment. It might be surmised that at least in some of the cases this physical defect was overlooked during the examination. This might have been so in isolated instances, in the case of volunteers, but such a view would not hold good in men belonging to the regular army. I saw more cases of hernia in men belonging to the latter, than the former branch of the military service. Our army in Cuba was not subjected for any length of time to hard marching or violent exertions of any kind, consequently the causes which led to hernia must be sought outside of such mechanical influences. Careful examination appeared to prove that in most, if not in all cases, the hernia was of recent origin. I attribute the hernia-formation principally to the relaxation of tissue, caused by disease and its effects, aided undoubtedly by the prevalence of intestinal affections which must have often resulted in increased abnormal intra abdominal tension. The uncertainty of the duration of the encampment induced me to advise against operative interference, and in most cases the general condition of the patients was such as to constitute in itself a strong contraindication to the performance of a radical operation. The patients were fitted with a truss and advised to have a radical operation performed after their general health was restored, after leaving the service or obtaining a furlough.

VARICOCELE.

The frequency with which varicocele is met with in men from 18 to 45 years was shown in the examination of 9901 volunteers in Camp Tanner, Illinois. As a member of the board of examiners, I was very anxious to obtain accurate information regarding this subject, and accurate notes were kept at the time. We found varicocele, slight, 992; medium, 692; large, 295. Of the slight cases 10 were double, 7 of the right side only; of the medium cases, 7 were double, and 4 of the right side only; of the large cases 4 were of the right side only. The percentage of varicoceles to total number examined was 21.17. Only six were regarded as physical disabilities, and those on account of size and pain. At that time I wrote a paper calling attention to the great frequency of varicocele in men of the age for military service, and claimed that ordinary varicocele was no valid objection to the enlistment of men for military duty. Of the more than 15000 men who returned from Cuba and were landed at Montauk, only five cases of varicocele applied for treatment at the surgical ward. In all of these cases the local symptoms were such as to warrant an operation. The operation was performed by excising through a straight incision, directly over the cord, the enlarged veins between double ligatures. The veins were carefully isolated by dissection from the spermatic cord and the accompanying artery. After excision the two stumps were brought together by a single catgut suture, and by tying over this a thread of one of the ligatures left long from each side. The stumps were buried by several fine catgut sutures with which the deep layers of the tissues were united. The external wound was always closed with horsehair sutures. Elongation of the scrotum sufficient in degree to require attention was corrected by transverse suturing of the external wound. The wound was sealed with collodion, a few narrow strips of iodoform gauze, and a pledget of absorbent cotton over which the usual dressing and bandage were applied.

Case 1.—John D. Deboer, aged 21, colored; Troop B, First Cavalry; has had varicocele for the last eighteen months. Enlisted five weeks ago. Marked ectasia of the spermatic veins on the left side with corresponding elongation of scrotum on

same side. He has had no pain, but much discomfort in hot weather from relaxation and dragging sensation. Operation under chloroform narcosis August 31. General health not much impaired.

Case 2.—William Cantwell, age 31, Company B, Sixteenth Infantry; has been in the service fourteen years. Varicocele appeared eighteen months ago. Since he entered the active service the swelling has often been painful, especially during forced marches and in hot weather. He is much concerned about his condition, and submitted willingly to the operation, which was performed under ether anesthesia September 3. On exposing the varicose veins it was found that the tunica vaginalis had remained patent from the external inguinal ring to the testicle, but contained no fluid. The veins were isolated with some difficulty from the cord and the spermatic artery. After disposing of the vein stumps in the usual way the tunica vaginalis was closed with fine catgut sutures over the cord. The scrotum was shortened by transverse suturing of the wound.

Case 3.—Wm. Reed, age 23, colored; Troop H, Ninth Cavalry. Made its appearance soon after his enlistment two months ago. The varicocele is of large size and gives rise to much pain on riding or walking any distance. Operation under chloroform narcosis September 3.

Case 4.—Robert Duseman, age 21, Second Volunteer Engineers. Entered the service two months ago. Six weeks ago, during drill, he bruised the left side of the scrotum, and attributes the varicocele to this cause. He complains of a dragging sensation in the testicle on the left side, the seat of the varicocele of medium size. Usual operation under ether, September 11.

In all of these cases the general health of the patients was not much impaired, and the wounds healed rapidly by primary intention.

HYDROCELE.

Hydrocele from puberty to the age of 45 occurs much less frequently than varicocele. Of the 9901 cases examined in Camp Tanner, we found only 49 cases of hydrocele of the tunica vaginalis and 18 of the cord. Only one case of hydrocele of the tunica vaginalis came for treatment to the surgical ward of Camp Wikoff.

Case 5.—John Craigie, Company E, First Artillery, a young soldier whose health had become greatly undermined by malaria, was sent from the medical to the surgical ward, for a painful affection of the left testicle of a few days' duration. Patient very anemic and emaciated. A few days ago, on recovering from his illness for which he had been sent to the hospital, the left testicle became painful and tender, accompanied by a gradually increasing swelling. He came under surgical treatment August 27. Careful examination revealed an acute hydrocele of the tunica vaginalis on the left side, without any palpable visceral lesions of the testicle or epididymis. The fluid, straw colored, was evacuated by tapping with a small trocar. One dram of equal parts of alcohol and carbolic acid was injected. The reaction was moderate and the patient left a few days later, the swelling gradually diminishing in size.

BONES AND JOINTS.

Only a few cases of injury and disease of bones and joints came under observation in the surgical department of the general hospital, but these isolated cases present features of interest sufficient to justify mention in connection with the subject of this communication.

Case 6.—Gunshot fracture of femur. S. M. Wetmore, age 25, trumpeter, Troop D, First Volunteer Cavalry, was shot through the right thigh at the junction of the lower with the middle third, the bullet passing in the antero-posterior direction, the wound of exit being on a higher level than the wound of entrance. The wounds were dressed with iodoform and healed by primary intention. Just before he was transferred from the hospital at Siboney to the *Relief* he became very much debilitated and manifested other and more characteristic symptoms of iodoform intoxication. A plaster cast was applied, and he was sent to the fever camp as a case of yellow fever—a diagnosis which was never confirmed by the physicians in charge of the hospital. He suffered from malaria, and his present condition indicates to what extent the malarial intoxication has advanced. He is extremely anemic, and emaciated to a skeleton. The spleen is much enlarged. The fractured limb is shortened two inches and a half; marked overlapping of fragments; union fibrous. Plaster of Paris bandage reapplied. Tonic and stimulating treatment.

Case 7.—R. Whittington, aged 25, First Volunteer Cavalry,

on August 14 was riding bareback, when his horse made a quick turn and in tumbling over an embankment the horse fell upon his left leg, producing an oblique fracture of the tibia about two inches above the base of the malleolus, and of the fibula about four inches higher. For some days the limb was placed in a fracture box, but it was found impossible to immobilize the fragments properly. During this time the patient suffered from pain and loss of sleep. August 27 he was placed under the influence of chloroform, the fragments were properly adjusted and the limb immobilized in a plaster of Paris splint extending from the base of the toes to the knee. Since that time he has been free from pain and has slept without the use of anodynes.

Case 8.—Maj.-Gen. S. B. M. Young injured his ankylosed elbow-joint, September 2, and received first aid at the surgical ward the next morning. During the War of the Rebellion he received two gunshot wounds of the right arm. One shattered the lower third of the humerus, the other perforated the elbow joint. After a prolonged siege of suppuration he finally recovered with ankylosis of the elbow-joint, in flexion at an angle of about 110 degrees, and in a position of marked pronation. September 1 he stumbled and fell, striking upon the hand and elbow. He complains of severe pain in and about the joint. The elbow-joint is swollen and very painful on pressure and manipulation. Ecchymosis over both condyles. There is some motion but no crepitation, indicating the existence of ruptured intra and periarticular adhesions. The patient states that this is the fourth time since the ankylosis occurred that it has been broken by injury of some sort. The limb was padded with a thick layer of cotton from the base of the fingers to the shoulder-joint, over which a light plaster of Paris bandage was applied. The patient was placed in charge of Major Nancrede, his attending physician, who a few days later substituted for the plaster dressing an angular wire splint. In less than a week he reported for duty at Camp Meade.

Case 9.—Thomas A. McDonald, age 24, Second Infantry. While in action before Santiago the stock of his gun was struck by the fragment of a shell, the arm was violently twisted and the radius fractured. The forearm now presents the characteristic "silver fork" deformity of an imperfectly reduced Colles' fracture. There is swelling of the wrist, inability to use fingers, and pain on attempted pronation and supination. Massage, manipulation and electricity advised.

Case 10.—Preston Guthrie, aged 34, Company F, Twentieth Infantry, re-enlisted three and one-half months ago. States that he cut his left arm two years ago. The wound was slow in healing and left a scar adherent to the underlying ulna. Nothing in the clinical history would indicate that the bone was affected at that time. A contusion of same region occurred while loading a transport in Cuba, which was followed by a complexus of symptoms pointing to the existence of a central osteomyelitis. An abscess which formed later ruptured through the old scar, an occurrence which was followed by prompt relief. A moderate discharge has continued since. Examination made August 26 disclosed two fistulous openings over the posterior surface and center of the ulna, leading into a central osteomyelitic cavity. Ulna at the seat of disease considerably enlarged. Through a straight incision the fistulous openings in the involucrum were exposed and the cavity freely laid open by chiselling. A sequestrum lying loosely in the bone cavity was removed and the granulations lining the cavity scraped out by a vigorous use of the sharp spoon. After thorough disinfection of the cavity the periosteum was sutured carefully, over which the wound was closed in the usual manner, leaving only a small space for gauze drainage. The wound remained aseptic and healed rapidly by primary intention.

Case 11.—George Oppel, aged 21, enlisted in the Second Infantry one month ago. He was admitted to the surgical ward with a fluctuating swelling over the inner aspect and a little above the left knee joint. Ten years ago he was struck in this region with a brick and suffered from an acute buritis. The bursa has been enlarged ever since, but has not been painful until recently. There is no tubercular history in his family. The swelling is flat and in circumference is as large as a medium-sized orange. On palpation no fluctuations can be felt, the sensation imparted being of a semi-elastic nature. The swelling is somewhat tender to touch and is painful when he attempts to walk. August 31, the patient being under the influence of a general anesthetic, the bursa was punctured with a small trocar in three different directions through the same opening in the skin and was thoroughly injected with a 5 per cent. solution of carbolic acid. Pressure was applied over the bursa and the limb immobilized upon a posterior splint. In the course of a week the swelling had almost entirely disappeared and the patient returned to his command for duty.

REMOVAL OF FOREIGN BODIES.

Two interesting cases of removal of a foreign body lodged in the tissues presented themselves for operative treatment.

Case 12.—Benjamin Nelson, age 23, Company F, Third Infantry. Came under observation and treatment September 6. Three years ago he fell backward against a window and sustained several cuts of the scalp by fragments of broken glass. The wounds healed rapidly without suppuration. After his recovery he was aware of the presence of a piece of glass which had remained encysted in the pericranial tissues ever since, without giving rise to any inconvenience until recently. A few weeks ago the scalp over the embedded foreign body was bruised, and since that time it has caused irritation and pain. The piece of glass could be readily outlined by palpation. On the day mentioned, without anesthesia, a straight incision parallel to the long axis of the foreign body was made. No suppuration within or outside of the capsule. The piece of glass was found surrounded by a firm capsule of fibrous tissue and measured two centimeters in length and two-tenths of a centimeter square at the end. The broken surface was irregular in outline. The wound was sutured with horsehair and union was found complete at the time of his discharge, September 11.

Case 13.—Sergt. Oscar F. Winter, age 52, Company F, Ninth Infantry, seventeen years in service. On July 2, while in the act of rising just behind the trenches, he was wounded by the bursting of a shell near him. He was confident at the time, from the sensation experienced, that he had received a blow from a large fragment of shell on the crest of the left ilium. He says a large ecchymosis formed at once and he could see no evidence of penetration. He was assured by a medical officer that he had suffered a contusion only, that there had been no penetration. He says, however, on being questioned, that a small rent existed in the clothing over the supposed contusion, but is very positive that he must have been struck by the convex side of a large piece of the bursting shell. An abscess developed soon after the injury was received and has discharged at a point near the anterior superior spine of the ilium and the resulting sinus has remained since. The patient has done duty without missing a day since he received the wound, until reaching Camp Wikoff. The existence of an abscess cavity and the history of an opening in the clothing led to exploration for a foreign body. The existing opening was slightly enlarged, under chloroform anesthesia, and exploration of the cavity with the finger located a shrapnell ball at about $3\frac{1}{2}$ inches downward from the opening of the sinus. Counter-opening was made at this point and the ball extracted. Tubular drainage, irrigation with peroxid of hydrogen and $2\frac{1}{2}$ per cent. carbolic solutions and moist carbolic dressing. Speedy healing of the wounds.

(To be continued.)

SOCIETY PROCEEDINGS.

Chicago Medical Society.

Regular Meeting, Nov. 2, 1898.

Dr. ARTHUR D. BEVAN, the president, occupied the chair.

Dr. E. J. SENN exhibited a patient upon whom he had performed a plastic operation following recurrent carcinoma of the breast.

Dr. A. R. SMALL reported a case of comminuted fracture of the patella. The patient was a victim of the Wabash Avenue fire on March 16, 1898. The left patella was broken into several pieces. The leg was put up in splints, and the result was excellent. It was not found necessary to wire the fragments.

Dr. ARTHUR D. BEVAN has demonstrated beyond doubt, by means of the X-ray, within the last two or three years, that bony union occurs in fractures of the patella treated by the conservative method, consequently it is not necessary to wire the fragments in many cases.

Dr. JOHN RIDLON exhibited a case of infantile paralysis affecting only the shoulder muscles. The child is 3 years of age. The case is undoubtedly one of anterior poliomyelitis, which came on when the child was a little less than 3 years of age, with the ordinary symptoms, but involving only the shoulder muscles. He said that Dr. Archibald Church has a photograph of a similar case affecting the arm muscles, but not the forearm and hand muscles.

EXTENSIVE FISTULA IN ANO.

Dr. J. R. PENNINGTON reported a case and exhibited the patient. She was referred to him by her physician, about eighteen months ago, then suffering from what is commonly

called a "horseshoe fistula." He said that this fistula is frequently, though not always, preceded by an abscess situated between the rectum and coccyx and beneath the raphe. In a typical case the pus burrows on both sides of the rectum and into the bowel dorsally between the sphincters. Cripps says "the matter originally collects in one or other of the ischio-rectal fossae, then makes its way behind the bowel to the fossa of the opposite side." From inspection and examination it is often impossible to measure the gravity of a case of fistula in ano. One may not suspect its complexity and extent until after the first incision has been made. The presence of only one external opening does not necessarily signify a simple fistula. He has seen some very extensive and complex fistulae with only one external opening. That was the condition of affairs in this case. In operating upon these cases it is important to recognize their conformation—especially is this true when there is one or more external openings on each side of the anus—and to bear in mind that these tracks have a home in common. Otherwise the operator is apt to proceed as though he had two separate and distinct fistulae with which to deal, and by following the advice given in some text books, slit up first one sinus, then the other, and, when too late to remedy, recognize that he has divided the sphincter in two or more places; that his patient has incontinence of feces and a remaining fistula—a very undesirable result, because to operate and not cure the patient is to bring disrepute on rectal surgery, and for the operation to be followed by incontinence of feces is to leave the patient in a most mortifying and loathsome condition, which is not apt to redound to the surgeon's credit.

Figure 1.

In this patient there was an external opening in the right buttock and an internal one on the left aspect of the bowel.

With reference to finding the internal opening when operating, Mathews says: "What this has to do with the operation for fistula, I must confess, I can not understand." Then he continues by saying that "if during the operation I introduce my grooved director and fail to find any internal opening, when one really exists, I push the instrument through the mucous membrane, then divide the tissues upon it, and search up the bowel from the cut, allowing the director to go as high as it will. Then, dividing again, we, of course, include any internal opening that may exist." Had Dr. Pennington followed this advice and pushed the director through the mucous membrane and divided the structures over it, incontinence would certainly have followed and the internal opening remained undivided. Beginning at the external opening he divided the fistulous tracks, as indicated by the heavy lines in the right buttock, to a point just beyond the track running into the bowel. He then discovered this latter fistula, which he thoroughly curetted and irrigated with a bichlorid solution. He purposely, at this seance, did not continue the division farther on the left side, but thought to try to close the canal extending on to the left labia by means of injections. This failed. In about three weeks after the first operation he opened this track, and to his surprise, found the two tracks leading off from this one to the very apex of the left ischio-rectal fossa. This necessitated a complete division of the

fossa. The dotted lines in Fig. 1 show fistulous tracks, and heavy lines, incisions made. The tuberosity of the ischium extended almost an inch above the base of the incision on the right side. The photograph, which was taken seven months after the operation, shows the great atrophy of the buttock, and gives only a meager idea of the destructiveness of this fistula.

Figure 2.

The Doctor called attention to the fact that the sphincter was not divided; there is no incontinence, and that the patient made an uneventful recovery; also, that by operating in this manner feces do not come in contact with the wound during defecation.

RECTAL INCONTINENCE.

The second case he reported was one of incontinence of feces following an operation for a simple fistula, while in the first case no incontinence followed operation for extensive and complete fistula. This patient says that she was operated upon two years ago by a good surgeon. She had been sent to him to have the function of the divided sphincter restored. Why an operation for fistula is followed by incontinence in some cases and not in others, it is difficult to say. Smith believes it to be due, not so much to the division of the sphincters as to the severing of the muscular fibers of the lower part of the rectum. Eemarch thinks it due to the division of the nerves supplying the muscles more than the division of the muscular fibers; while Kelsey holds to the theory that it is due to the vicious cicatrization, by which the divided ends of the muscles are not brought into apposition. The Doctor's own belief is that it is due as much to a want of technic in operating and inefficient after-treatment as to any other one cause. In bad cases flatus is passed without treatment as to any other one cause. In bad cases flatus is passed without the slightest warning, and the contents of the rectum may be discharged into the clothing before the sufferer can reach the toilet room. This condition is often so mortifying that patients express a desire to die rather than to live. It is very gratifying, however, to know that most of these cases can be cured or at least made comparatively comfortable. In the less severe cases, much benefit may be derived from the use of drugs and from regulating the diet. It must be remembered, however, that in directing palliative treatment there is a great variation in peristaltic action; some persons defecating two or three times in twenty-four hours, other only once in forty-eight to seventy-two hours. In the former the stools are semi-solid, while in the latter they are hard and scybalous-like. Hence the control of the feces in a patient with a weakened sphincter may be easy or difficult. In the more severe cases, where operative interference is indicated, the surgeon has ample opportunity to exercise all his surgical ingenuity in devising an operation for relieving this condition. In those cases where the remaining segments show signs of contractility, measures looking to their union and restoration of the muscle will be more or less successful. Among the measures may be mentioned: 1, Tait's operation upon the perineum; 2, application of the cautery; 3, exposing the cut ends of the divided sphincter, and their reunion by sutures. But when the nerve supply has been destroyed, the muscular segments greatly atrophied and displaced by cicatricial tissue, restoration becomes impossible. In such cases the operation devised and successfully performed by R. Gersuny of Vienna, and subsequently by A. P. Gerster of New York, which consists

in separating all the coats for two and a half inches up the bowel, then securing the gut and twisting it upon itself in an arc of 360 degrees, and stitching it to the skin by sutures, will perhaps give the best result.

Dr. ALEXANDER HUGH FERGUSON reported a case of floating kidney, tubal pregnancy and gall-stones, in one patient, all treated surgically on two different occasions. The extra-uterine pregnancy occurred in the right tube. The patient was a private case, 30 years of age, and was referred to him by Drs. Franklin and Bergeron. She presented herself, complaining of pain in the umbilic region and of a tumor in the right lumbar region, which was movable. A diagnosis of floating kidney was apparent. The diagnosis of gall-stones was more difficult. In May last she had her first attack. She retired, after a hard day's work, and about three o'clock in the morning was seized with a sudden pain in the region of the umbilicus which woke her up. Vomiting was present. Hot fomentations were applied and the pain subsided as suddenly as it appeared. This was a point he wished to particularly emphasize as diagnostic of gall-stones attempting to leave the gall-bladder and falling back again. Two or three days after that she had a second attack. Pain came on suddenly, again about three o'clock in the morning, and was referred to the umbilic region, with vomiting. There was tenderness, on pressure, over the region of the gall-bladder. She had slight pyrexia, and a physician was called, who gave morphin. One dose of morphin and the application of hot fomentations sufficed to relieve her second attack. Five days later she had a third attack. The pain came on suddenly, and was again referred to the umbilic region, accompanied by vomiting. There was more tenderness over the region of the gall-bladder than during the other attacks. In the second day of the attack slight jaundice appeared and persisted for a week. This attack disabled her for about ten days. From the first week in June until July 31, when he saw her, she had had six or eight attacks. After this attack, a tumor was felt for the first time in the lumbar region. This was correctly diagnosed as a floating kidney. A rubber bag inflated with air was bandaged over it; when she would have attacks of colic they would be relieved by the inflated bag pressing the kidney upward and backward, but the pain would not completely disappear. Upon manipulation it was found that the kidney could be pushed upon the brim of the pelvis over to the median line, and could be swept back to its place with that characteristic slip that is found in floating kidneys. Manipulations over the gall bladder at this time elicited very little tenderness, except when he gave a deep prod. If stones are present in the gall-bladder, patients usually complain of a pain when a deep prod is given them. From the above-mentioned data he made the double diagnosis of floating kidney and gall-stones.

An incision was made on the side to fix the floating kidney, through which the gall-bladder was explored and 114 gall-stones removed by the lumbar route. He believes it unwise to anchor the gall-bladder in the lumbar region because we would surely have a fistula; therefore, he made a button-hole incision in front, opposite the cartilage of the ninth rib, and the gall-bladder was sutured to its internal aspect and drained. He drains almost all gall-bladder cases. The woman made an uninterrupted recovery, left the hospital at the end of three weeks, and two days after had an attack of biliary colic. This attack came on suddenly; was accompanied by tympanites and tenderness which lasted for several days, when a second attack came on. This attack was more severe, was accompanied by vomiting and slight jaundice. A third attack was still more severe. The pain during these attacks was always referred to the umbilicus as in the previous attacks, and this is of importance from a diagnostic standpoint. Pain began in the region of the right ovary during the third attack. This new complication predominated during a fourth attack of biliary colic, with the greatest amount of pain in the right pelvis, and symptoms of internal hemorrhage. All the time jaundice was intermittent. Her husband wrote to him about her condition, and he told him to send her back to the hospital, where Dr. Ferguson made an examination, found tenderness in the region of the cystic duct, and a great deal of tenderness in the right ovarian region. Upon vaginal examination he found a large, soft, boggy mass. She had menstruated just a week before entering the hospital the first time. He found milk in the breasts, and made a rather bold diagnosis of stone plying between the cystic and common ducts and extrauterine pregnancy. She was placed upon the operating table, and an incision made through the right rectus muscle low down, so as to deal with the mass in the right pelvis. The abdomen being opened, clotted and liquid blood was noticed. The pelvis was full of it. A mass was seen in the right pelvis; this was covered with a gauze pad for the time being. Going on the

left side of the patient, entering the abdominal cavity, passing two forefingers of his left hand through the foramen of Winslow at the junction of the cystic and common ducts, he felt an irregularly-shaped stone. In trying to force it up into the gall-bladder, it slipped away and went in the direction of the common duct. He went after it again and pushed it into the gall-bladder; then incising the gall-bladder at the site of the former wound, which had closed, he slipped the stone out. He then demonstrated that the ducts were pervious, by forcing water through them into the duodenum. He exhibited the fetus, which measured three inches and a half from vertex to nates. Both fetus and placenta were found in the tube. The last operation was performed six weeks ago. He exhibited the patient and specimens.

Dr. ARTHUR D. BEVAN, in the discussion, narrated a case in which a diagnosis of gall-stones, floating kidney and appendicitis was made, an operation successfully performed and the diagnosis verified.

Dr. JAMES B. HERRICK contributed a paper on

THE TREATMENT OF ULCER OF THE STOMACH BY REST IN BED AND RECTAL FEEDING.

He regarded the writing of a paper on this old subject as warranted by the fact that many modern text-books make no mention whatever of rectal feeding in the treatment of ulcer; others recommend its use only in severe or exceptional cases, while a relatively small number advocate its employment in all cases. Physicians, too, often oppose the treatment or give it a half-hearted approval. By rest in bed and rectal feeding, the natural tendency of the ulcer toward recovery is encouraged by the removal of all mechanical and chemic irritation, so far as this is possible.

He said that several objections have been made to rectal feeding. The objection that the rectum will not submit to repeated enemata, but will give out, is answered by the fact that when suitable enemata are properly administered, the rectum will tolerate this method of treatment for many days or many weeks. Some contend that the nourishment is not absorbed, but its absorption is proven by experiment as well as by clinical observation. The argument against this method, that the patient can not stand it, that he will become too weak, can not endure the thirst, hunger, and weakness, is answered by the fact that patients do stand it and without complaining, and that when the matter is clearly set before them they submit to this method willingly. The objection that the treatment is inefficient and unsuccessful is answered by the successful results in the hands of physicians who have tried the method carefully, and by the fact that the trend of medical opinion is setting in toward rectal alimentation in all cases of ulcer of the stomach.

In carrying out the treatment it is important to secure the consent of the patient by a clear explanation of the reasons for the treatment, the method of carrying it out, the probable length of time required, etc. This relieves worry and restlessness on the part of the patient. The bowels should be emptied by a preliminary laxative and cleansing enema. Absolute rest in bed should be required for from two to six weeks. Nothing should be given by the mouth, not even water, for from three days to three weeks. Nourishing enemata should be given at regular intervals, say of four hours, by means of a soft rubber tube inserted high into the rectum. Enemata can be given once in twenty-four hours, a period of eight hours' rest, as, for example, from midnight to 8 o'clock in the morning, being desirable. The quantity and kind of food, as well as the hours, can be varied in individual cases. A simple enema of water is to be given every morning. This may be retained, in which case it quenches thirst; it may be rejected, acting as a cleansing enema. As pain, tenderness and vomiting cease, the enemata can be gradually withdrawn, and peptonized milk or other light diet carefully substituted by the mouth. The patient should be allowed to get out of bed only after rectal alimentation has been entirely stopped. It is best to keep the patient in bed for at least four weeks. Iron may be necessary for the chlorosis so commonly present. This should only be given when a light diet is tolerated. The results are an almost immediate lessening of pain, vomiting and nausea. There may be emaciation and weakness; that will disappear quickly when stomach feeding is resumed. A cure is the result in the larger number of recent cases. In old cases a cure, or at least improvement, will follow. Deep ulcers, very extensive ulcers, large amounts of scar tissue or adhesions may interfere with a perfect recovery. This rational method of treatment, allowing nature to work the cure, deserves the warmer endorsement of text-books and physicians, particularly as medicinal treatment is so unsatisfactory. It should be employed in every case, either mild or severe.

Dr. HENRY GRADLE read a paper on

PHLYCTENULAR OR SCROFULOUS OPHTHALMIA.

After referring to the frequency of this affection and its preponderance in girls, he described it as a disease of childhood, seen rarely after puberty and then only in patients who had been subject to it since early childhood. The characteristic lesion is the phlyctenule, not a vesicle but a translucent papule (of leucocytes), which in typical cases disappears by absorption in five to eight days. The serious aspect of the disease, however, is the liability to relapses, often in multiple form, the frequent delays in the disappearance of the phlyctenules, and particularly their transformation into larger papules: into corneal infiltrates, which often ulcerate; or into diffuse patches of superficial keratitis with new formation of blood vessels. All these manifestations are but metamorphoses or sequelæ of phlyctenules.

The causes of such an unfavorable course are often associated with adjoining lesions, the proof of which is furnished both by the coexistence and by the influence of treatment of these associated lesions upon the phlyctenular process. Among these injurious conditions are catarrhal conjunctivitis, and especially the transient smooth hypertrophy of the superior retrolarval fold, called by the Germans *Schwellungskatarrh*. For the latter condition the author recommends nitrate of silver (if necessary, in the strength of 10 per cent. solution), to be applied strictly to the swollen fold of the conjunctiva. Important, likewise, is ulcerative blepharitis, to be treated with the stick of nitrate of silver and the yellow oxid salve.

Eczema is so frequent a coincidence that the disease has been termed "eczematous kerato-conjunctivitis," a name which the writer considers inappropriate, as the eye affection is neither clinically nor anatomically analogous to cutaneous eczema. Eczema of or near the eyelids exerts a distinctly injurious influence upon the eye lesions. Whether eczema at a distance is of equal importance is doubtful.

Purulent rhinitis is often, but by no means always, associated with phlyctenular disease. With it there is nearly always hypertrophy of the pharyngeal tonsil—adenoid vegetations. The latter condition requires surgical removal from intrinsic indication, but how much the nasal disease predisposes the eye to relapses, or to persistence of the phlyctenular lesions is an open question.

The direct cause of phlyctenular eruption is as yet unknown. The search for constant or characteristic microbes has been unsuccessful, and the most extensive researches by Axenfeld led to negative results. It is certain, however, that the exceptions to this rule are merely apparent, not real, for scrofulosis is at present a vague term, and not recognizable. The researches of Koch, and especially his disciple Petruschky, have made it almost certain that scrofulosis is identical with mild chronic poisoning of the juvenile organism by the toxins of the tubercle bacillus, usually hidden in some lymphatic gland. But some of the manifestations of scrofula—the tendency to eczema and the enlargement of the pharyngeal tonsil—are not themselves tubercular lesions, or due to the presence of the tubercle bacillus in the diseased locality, but they are evidently local chances due to other causes, favored, however, by the undermining of the resisting power of tubercular poisoning. The author regards phlyctenular ophthalmia in the same light, namely, as a lesion occurring mainly—if not exclusively—in a soil predisposed by poisoning from some forms of "latent" tuberculosis—in the lymph-glands. This view was supported by the characteristic reaction of some diagnostic injections of tuberculin in four cases.

On the basis of this view, and from extensive experience, he endorses the hygienic treatment generally adopted in tuberculosis, namely, an out-door life, proper feeding, baths, and, if indicated, cod-liver oil. These measures seem to protect fairly well against relapses, but their influence requires too long a time to be of immediate benefit as far as the attack at the time is concerned. In the local treatment he recognizes the influence of calomel dusted into the eye, especially when used two or three times daily. Atropin is of decided influence when there is pronounced ciliary irritability, and especially when the pupil is narrowed or resists the dilating influence of the drug. But whenever the process is not accompanied by much irritation, or when the pupil yields at once, atropin seems to exert no influence of any kind.

Dr. WELLER VAN HOOK described a hernia operation designed to do away with the need of splitting the aponeurosis of the external oblique muscle, in order that, in case of suppuration, the state of the patient need not be aggravated by the enlargement of the external ring. After treating the sac by partial amputation and drawing the stump back up the canal by means of a curved artery forceps and fastening it, after

Kocher's plan, to the tissues above the cord, he dissects up the aponeurosis of the external oblique from its muscle and frees Poupart's ligament by the finger introduced into the canal. A handled curved needle, unarmed, is then passed under Poupart's ligament at a point sufficiently below the cord to prevent the pinching of the cord at the internal ring. The point of the needle is received under the finger in the inguinal canal and is carried under the cord (raised by an assistant) to a point behind the inner pillar. The needle is then passed through the internal pillar and its point appears projecting through the aponeurosis of the external oblique. The needle is then threaded and withdrawn. The forefinger is next passed up the canal behind the cord until the inner portion of the thread is felt between the external oblique muscle and its aponeurosis. The finger is hooked around the thread in order to pull it out of the external ring along with the finger. Then the needle is introduced at a point about one-fourth of an inch inside the first point of introduction through the aponeurosis of the external oblique into the canal; it is guided with the finger down the canal to the external ring and is there again threaded with the suture end which was brought out by the finger. It will be seen that when the needle is withdrawn we have a suture by which we can draw together the internal pillar and the most posterior portion of Poupart's ligament. As many such sutures as may be desired are thus introduced and the external ring is closed by sutures in the usual way.

This operation would be impossible only in those rare cases in which Kocher's and McEwen's operations could not be performed, viz., when an inspection of the internal ring is imperative. There is no risk of injury to important structures, and the amount of time required for the operation is scarcely more than would be needed for an ordinary Bassini.

San Francisco County Medical Society.

November Meeting.

Dr. JELLINEC presented a paper, with a demonstration of a case, on

SPORADIC CRETINISM.

The first case reported was that of a female child, 4 years and 2 months old when first seen. The parents were Jews, but there was neither any family history nor any particular taint that could be ascertained. Up to the age of 9 months the child had developed normally, but after that time she began to exhibit the various indications of the disease. When first seen, about the middle of August, she weighed 25½ pounds and presented a perfect picture of cretinism. The could not be found the slightest trace of thyroid gland, and its absence was declared by the Doctor. Constipation was very marked, the bowels moving only every fifth to sixth day, and then only under cathartics. Treatment by tablets of thyroid extract was commenced, August 26. The dose at first was one-half a tablet per day, or the equivalent of .15 gm. of the gland. No effect was observed from this dose, at the end of a few days, so the quantity was increased to .3 gm., or one tablet per day. This had a very decided effect, for it produced copious stools and the child began to lose flesh very rapidly. The dose was therefore reduced to the former amount, one-half tablet. October 11, the child had lost two and one-half pounds, and was quite perceptibly improved. It was still a very well-marked case of the disease, and the Doctor expressed his intention of continuing the thyroid treatment and reporting the case to the Society from time to time.

The second case reported was much the same as the first, only it had been under treatment for some thirteen months, and consequently showed very marked improvement. When first seen the child was 5½ years old, 61 cm. in height, and weighed 19 pounds; its vocabulary consisted of nine words, most of them being so poorly articulated that they were unintelligible to any one unacquainted with it. The fontanelles were still as much unclosed as at the time of birth; there was no apparent thyroid, and there was every indication of cretinism. July 26, 1897, the treatment by thyroid gland tablets was commenced by the employment of one-half tablet per day, being equal to .15 gm.; this small dose had a very marked effect on the first day, producing four copious stools. The dose was therefore reduced to one quarter tablet, and then gradually increased to three tablets a day; at the end of a year the child was taking nine tablets a day, had grown 9.4 cm. in height and weighed 27 pounds. A look of intelligence had made its appearance, and the vocabulary was quite considerable; the fontanelles had closed. The child at this time could run about and play. The Doctor said that the size and nature of the dose would depend upon the individual case under treatment, but that the thyroid tablets would have to be taken throughout life.

Dr. WM. FITCH McCHENEY said, in discussion, that the name "cretinism," by custom, is applied to those cases in which there is a congenital deficiency in the thyroid gland, and the name "myxedema" is confined to those cases in which the deficient secretion of the thyroid is an acquired characteristic. Where cretinism occurred only occasionally in a community, the term "sporadic" was applied. As to the pathology, three principal theories have been advanced to explain the conditions we find; a total absence of the thyroid gland; atrophy of the gland; goiter, in which cases we find a cystic or tumorous growth in the thyroid, the foreign growth limiting the physiologic activity of the gland, and thus preventing the proper amount of its secretion. He did not believe that there was often a total absence of the gland, for the reason that so many cases which before death had been pronounced to be without the thyroid, showed on postmortem examination that there was really a rudimentary gland present. He thought that atrophy or neoplastic growth would explain almost all of the cases encountered. He said that, as Dr. Jellinec had mentioned seeing seven cases of this disease, and as Osler had some short time ago given a résumé of all the cases reported in the American press, which amounted to sixty in all, Dr. Jellinec had been very fortunate. As to the question of administering the thyroid gland tablets all through life, he did not agree with Dr. Jellinec. In his opinion, this was not necessary; experience seemed to have shown that if the gland was employed for a time, a certain improvement would result, but that improvement was noticed only up to a certain point, and that beyond that point the further administration of the gland had no effect whatever.

Dr. JOHN WAGNER asked as to the details of administration; when the tablets were given and how; whether with meals, before, or after eating, and whether dry or in what form. He had had no experience with the thyroid treatment, but he had hoped to get some information from the paper of Dr. Jellinec.

Dr. JELLINEC said, in reply to the discussion, that he had simply intended to demonstrate a case which he would again show to the Society after it had been under treatment for some time. He considered the terms "sporadic cretinism" and "myxedema" as synonymous terms. There could be no rule as to the method of giving the thyroid extract; circumstances must determine the method in each case. In some cases he gave it in one dose, in the morning dissolved in milk or soup, say of two or more tablets; he gave it in two or three doses in the same solutions. He had seen but two of the cases in this country, the others he had met with abroad, where they are very common, so common in fact, that nothing more is now written on the subject. Where there was total absence of the thyroid gland, as he thought was often the case, the tablets would have to be taken throughout life, though they could be suspended from time to time, for such periods as the patient could stand without the medicine. If the individual was not himself the possessor of a thyroid gland that could secrete, he would have to be artificially provided with this very necessary secretion.

Dr. A. MILES TAYLOR presented a paper on, and a report of a number of cases of

VAGINAL HYSTERECTOMY.

There were forty cases in all, with one death, and as the cases were very mixed, many of them being pus cases, the results were good. He claimed that they were much better results than could have been obtained in the same cases if abdominal operations had been undertaken in the same circumstances. Vaginal section for pelvic diseases was in every way, in his opinion, far superior to abdominal section, except in very rare cases. The patient is carefully prepared, when circumstances permit and placed in the lithotomy position; the uterus is then curetted and the instrument put aside and not again used during the operation; the posterior cul-de-sac is the most convenient point of entrance, generally, and the opening here is easily made. The cervix can then be drawn up and the opening dilated; with the patient then changed to the Trendelenburg position an ocular examination can be made that will be fully as satisfactory as the ocular examination by the abdominal incision, for with the use of the proper retractors the vaginal opening may be made as large as the abdominal, and the distance to the parts within is about the same in the two cases. The technic of the operation in its various phases was then gone over by the Doctor, and a number of cases reported. Some of the cases mentioned are abstracted as follows:

Case 1.—Pelvic disease following a miscarriage. There had been great pain for a year, and for six months previous to the operation she had been delirious during her menstrual periods. When seen she had a temperature of 104, pulse of 120, and

great tympanites and tenderness. The finger was introduced into the vagina, the posterior cul-de-sac ruptured, and a great quantity of pus poured forth. The pelvic cavity was well irrigated with salt solution, and one tube removed; the other tube had sloughed off and was washed out. The opening was packed with gauze, and the patient did well till the fifth day, when her temperature suddenly went up to 105, again rose to 106 at eight o'clock at night, and she died in a few hours. Postmortem examination showed the cause of death to be septic cerebral meningitis.

Case 2.—Woman of 26 years; married; pain and discharge almost continuously since marriage, three years before; one month before seen, had been operated on for a lacerated cervix and perineum, but with only trifling benefit. Operation was performed per vaginam, and on the incision being made a large amount of pus was evacuated; the pelvic cavity was irrigated and a large mass appeared which proved to be the left tube in the guise of a huge pus sac. Both tubes were removed and the pelvis irrigated with bichlorid solution, 1 to 8000, followed by salt solution. The wound was then packed and the patient made an uninterrupted recovery at the end of the third week. She has since remained well and has no pain nor discomfort.

Case 3.—Woman of 18 years, married for four months; for two months had not menstruated; had been pronounced pregnant; severe pain came on suddenly when arising from the table. The diagnosis of ruptured extra-uterine pregnancy was made and operation decided upon at once. Incision in posterior cul-de-sac was followed by free hemorrhage. The fetal mass was found, and the bleeding point located and tied off; the pelvis was then irrigated and packed and the patient made a good recovery.

A number of other cases were reported, and the Doctor then summed up his conclusions as follows: The vaginal route is to be preferred for the reasons that there is less shock, less danger, no danger of hernia, it is easier to work on any of the pelvic organs, the incisions are easier, the examination of the pelvis more complete, drainage can be perfect, and it leaves the patient much more comfortable than the abdominal operation, for movement in bed is not prevented after the operation. Conservative surgery on the ovaries and uterus was the great desideratum of modern surgery, and it is far easier to make plastic operations on these organs per vaginam than by the incision through the abdominal walls.

Dr. F. B. CARPENTER said that the vaginal operation was not to be preferred in the majority of cases, but in some it was undoubtedly the best. There was certainly less shock in the vaginal operation, but when many adhesions had to be broken up the abdominal route was preferable. He did not consider that irrigation was a good measure in most cases, and indeed in many cases where there was pus in the tubes, it had been so long retained that it had ceased to be septic pus and, if liberated into the pelvis, could not and did not do any damage. He considered the operation per vaginam much more difficult than the abdominal operation, and thought its advantages more than counterbalanced by its disadvantages.

Dr. J. HENRY BARBAT thought that the results of the forty cases reported could not have been better, for the cases were almost all very grave ones, and the occurrence of a single death showed that great skill had been employed. He was of the opinion that the special method followed by any operator who had the requisite ability was the best for that man, but was not the best necessarily for all men; some men could get better results by the vaginal method, and others found the abdominal method more satisfactory in their hands. It was largely a matter of the personal equation. In some cases the vaginal operation had much the advantage over the abdominal, but this was not always the case.

The officers of the society for the ensuing year were then elected. Wm. H. Davis was elected president, E. F. Kelly, vice-president, Philip King Brown, treasurer, and Geo. H. Evans, secretary.

SELECTIONS.

Toxins and Antitoxins.—The proceedings of the Royal Society for July 29 contain a communication by Drs. C. J. Martin and T. Cherry, on the nature of the antagonism between toxins and antitoxins. The authors refer to the discussions of this subject by Behring, Buchner and others beginning in 1894. They refer to Calmette's experiments in 1895 with cobra poison and its antitoxin, which seemed to prove that the toxin of snake venom does not interact with its antitoxin *in vitro*, but only *in corpore*, and therefore its action can not be explained

as a simple chemic operation between the two. The sum of these and other experiments was that certain measures being found which destroyed either the toxin or the antitoxin, when these measures were applied to a mixture of the two *in vitro*, the one not affected remained active while the other became inert. The inference was that the interaction did not take place *in vitro*. The authors, however, point out that the absence of any account of the time during which the interaction should be permitted to continue, as a factor in the experiments, vitiates their results; and, while admitting that the same results can be repeated, they consider the conclusions founded on them unjustified, and assert that by modification of the factors—time, temperature and active masses—exactly opposite results may also be obtained. Their experiments tend to prove that since the toxin of diphtheria will pass through a gelatin filter, while the antitoxin will not, a mixture of the two *in vitro* would become separated by filtration and the filtered toxin would be active, unless it were previously neutralized by contact with the antitoxin *in vitro*. They found that a mixture of the proper neutralizing amounts, when left in contact at 30 degrees C. for two hours, was not active after filtration, proving thus that the antitoxin had neutralized the toxin. They say: "As the experiments are so simple as not to leave any possibility of experimental error, we turn our attention to our existing difference in the conditions under which Calmette and ourselves worked. As previously pointed out, Calmette absolutely neglected the possible influence of time, temperature and the relative proportions of the active masses of the toxin and antitoxin present in his mixture. Up to the present we have investigated the value of the factors, time and proportion of active masses, and have shown that these are most important. Indeed, by altering either the one or the other, we can produce results which, if these factors be neglected, would lead to diametrically opposite conclusions."

We have not yet determined the influence of temperature upon the rapidity of the reaction, but our results so far seem sufficiently conclusive to decide the question and leave no room for doubt that the antagonism between the toxins of diphtheria and snake venom and their relative antitoxin is due to a direct chemic action which takes place between them, and further, that the opposite conclusion come to by Calmette, and presumably those of Wassermann, Nikanarow and Marengi, were due to their disregard of the value of time as a factor in such chemic action." It may be remarked, in conclusion, that these experiments, of undoubted scientific value, of Drs. Martin and Cherry were conducted in the laboratories of the University of Melbourne, Australia, with the teaching staff of which institution both these young pathologists are connected. —*N. Y. Med. Jour.*, September 10.

Located by Skiagraphy.—Dr. de Schweinitz has recently reported a case of a piece of steel imbedded in the sclera for two and one-half years, localized by the Roentgen rays, according to Dr. W. M. Sweet's method. In November, 1895, a piece of steel entered the eye, probably near the corneal margin at the inner side. In March, 1896, a radiograph of the eye indicated that a foreign body was located in the orbit at the upper nasal side. It was deemed expedient to make search for it. In February, 1898, when Dr. de Schweinitz first saw the case, V. = 6/20; eye quiet; marks of a previous iritis; capsule and lens partly opaque; floating opacities in the vitreous. With undilated pupil no foreign body could be detected in the vitreous or in the coats of the eye. A series of skiagraphs located it 11 mm. below the center of the cornea, 3 mm. to the nasal side, and 10 mm. back of the cornea. A second series taken while the eye was rotated as far as possible downward shows a movement of the body practically equal to the extent of the rotation of the eyeball downward. This would seem to determine the sclera as the site of the body. With wide pupil dilation a small patch of choroidal atrophy streaked with pigment, and

with a black center, exactly in the position indicated by the radiographs, could be seen. Just over this location the sclera was sensitive to the touch of the probe. The field of vision was markedly contracted, and there was uncertain limitation opposite where the body was supposed to lie. The patient refused to permit an exploratory operation. Dr. Sweet has had an interesting experience in the localization of foreign bodies in the eyeball by his apparatus. The various methods that have been employed resolve themselves into a determination of the angle of the X ray tube with the foreign body and with one or more dense objects situated near the eyeball. Approximate results have been obtained from a study of the shadow of the foreign body in relation to the shadows of the orbital bones, but owing to the variations in the position of the eyeball, which have been shown by the investigations of Cohen to amount in healthy individuals to as much as 10 mm. behind the edge of the orbit and 12 mm. in front of the same, this method does not equal the accuracy possible by other means. Whatever form of indicating objects is used in working out the position of the foreign body, certain factors are essential to accurate results: 1. A tube should be used which may be run at high vacuum, in order that the rays readily penetrate the bones of the head. 2. The patient should be in the recumbent posture to ensure steadiness of the head and body. 3. The visual axis should be parallel with the plane of the plate at the side of the head, or if it deviates, the angle should be measured and allowed for in the determinations. 4. The situation of the indicating objects with respect to the center of the cornea in each individual case should be known, otherwise the determination of the location of the foreign body will vary with the varying situation of the eyeball in the orbit in different persons. 5. The angle of the tube with the indicating object must be accurately measured. The two indicators being parallel with each other and with the plate, the distance the shadow of one of the balls is posterior to that of the other is the measure of the distance that the source of the X-ray is carried to the front. The method has been employed in a number of cases of suspected foreign bodies in the eyeball and orbit, in seven of which the shadows of the bodies were obtained on the plate and their position indicated. Three of the cases were gunshot injuries, in which the findings were not verified by subsequent operation.—*Maryland Medical Journal*.

PRACTICAL NOTES.

Telelectro-Therapeutics.—Gerest of Lyons cures hysteric paralysis by a series of electric discharges in the neighborhood of the patient, without contact. The effect is evidently similar to that of suggestion.—*Munich Med. Woch.*, November 1.

Dry Treatment of Prurigo.—The parts are dusted with a power of oxid of zinc, salicylic acid and talcum, and covered lightly with a protecting bandage changed every forty-eight hours. In two weeks there is no trace of the affection.—A. Monti: *Semaine Méd.*, November 2.

Orthoform for the Larynx.—Kassel prevents the coughing that usually follows the insufflation of the dry powder in anesthetizing the larynx, by injecting it in an emulsion of 25 parts orthoform to 100 parts olive oil, with the ordinary laryngeal syringe.—*Munich Med. Woch.*, November 1.

Dauger Signal in Chloroform.—R. Lehmann states that if the patient keeps his eyes completely or partially open during the narcosis, and opens them whenever you try to close them, you can expect some accident, more or less severe. This phenomenon was noted 21 times in 329 anesthetics, and in each one there were either continuous vomiting, arrested respiration, peculiarly protracted agitation, or asphyxia and syncope, requiring artificial respiration.—*Semaine Méd.*, November 2.

Insomnia in Advanced Arteriosclerosis.—Professor Edgren of Stockholm has been very successful in inducing refreshing sleep without morphin, with rectal injections at night of antipyrin, 1 gm., diuretin 1 to 2 gm., or chloral 2 to 3 gm., in the advanced stages of arteriosclerosis when the heart suffers and insomnia is frequent, with more or less dyspnea, vertigo, restlessness, even delirium and hallucinations.—*Semaine Méd.*, October 26.

Sero-therapeutics of Tuberculosis.—Maksutow has obtained a serum from the juice extracted from a tuberculous abscess on a cow, chopped fine, in a aqueous, alcohol-glycerin solution. Injected after filtering, into guinea-pigs and goats, it prevented infection and arrested lesions already under way. Every test was successful.—*St. Petersburg. Med. Woch.*, October 29.

Accidental Nervous Enteritis.—When, in consequence of exposure, violent emotion, insomnia, excesses, or other causes affecting the alimentary canal, there is distress and pain in the epigastrium and more or less diarrhea, the following prescription will be found agreeable and promptly effective: Tincture of opium x gtt., orange flower water 20 gm., old rum and simple syrup aa 40 gm. Mix in a glass of water and drink rapidly.—*Journ. de Méd. Paris*, October 30.

Ankle Clonus in Tabes.—Babinski considers the partial or total abolition of the ankle clonus an indication as important in the diagnosis of tabes as Westphal's sign. In most cases of tabes there is more or less disturbance in both the knee jerk and ankle clonus, and in the rare cases in which a single reflex is affected, it is as liable to be the one as the other. He also differentiates true sciatica by the abolition of the ankle clonus, the patient kneeling on a seat.—*Progrès Méd.* October 29.

Gelatin in Aneurysms.—This treatment, described in the *Journal*, page 1180, has caused two deaths; one patient dying from fresh tuberculosis a few months later, probably caused by compression of the pulmonary artery by coagulations. The death of the second patient is more directly to be attributed to the treatment, as it produced coagulations in the neck and the rapid ischemia of encephalus. Huchard, therefore, advises weak concentrations, 8 to 10 days intervals and the patients in absolute repose. "With these precautions, gelatin is a rational and valuable means of assisting nature in her curative processes."—*Bulletin de l'Acad. de Méd.*, October 25.

The Migrainator.—It is proved by experience that headache may sometimes be relieved by compression of the head; persons suffering from headache instinctively put their hands on their temples and feel great benefit therefrom. To make this compression more efficacious, Dr. Sarason has suggested an instrument, which he describes in the *Deutsche Med. Woch.* It consists of two plates, which are firmly pressed on the temples by a spring, and the device looks very like a double truss. By the compression of the temporal arteries the circulation of the blood in the head is regulated and pain is relieved, especially in angiopathic hemicrania. The apparatus is termed a "migrainator." It is made in Munich.—*London Lancet*, October 8.

Ringworm of the Scalp Treated by Sodium Chlorid.—Dr. Perkins writes to the *London Lancet*, that for fifteen years he has treated every case of ringworm which has come under his care with chlorid of sodium, and with complete success in every case. The first case in which he used this treatment was a chronic one of five years' standing. The child was well in three weeks and had no return. Many of the cases which have been attended since have been of chronic character. His method is the following: Have some chlorid of sodium finely powdered and then mix with a little vaselin to make an ointment. The affected part having been shaved, rub this ointment in well night and morning until the place is sore; this takes from two to four days. Then use some simple application to aid the healing of the part. When well from the soreness, the hairs will be found growing healthily and the tinea trichophyton destroyed.

THE JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION
No. 61 Market Street (Occidental Bldgs.), Chicago, Illinois.

MEMBERSHIP IN THE AMERICAN MEDICAL ASSOCIATION.

This is obtainable, at any time, by a member of any State or local Medical Society which is entitled to send delegates to the Association. All that is necessary is for the applicant to write to the Treasurer of the Association, Dr. Heary P. Newman, 100 Washington St., Chicago, Ill., sending him a certificate or statement that the applicant is in good standing in his own Society, signed by the President and Secretary of said Society. Attendance as a delegate at an annual meeting of the Association is not necessary to obtain membership.

On receipt of the subscription the weekly JOURNAL of the Association will be forwarded regularly.

Gentlemen already members of the Association should send their annual subscription to the Treasurer, or direct to the JOURNAL office.

All communications and manuscript of whatever character, intended for publication in the JOURNAL, should be addressed to the Editor, and all communications relative to the business of the JOURNAL, proof-sheets returned, or in regard to subscriptions, should be addressed to THE JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION, 61 Market Street (Occidental Buildings), Chicago.

Original communications are only received with the understanding that they are exclusively contributed to this JOURNAL.

SATURDAY, NOVEMBER 26, 1898.

ON THE BACTERICIDAL FUNCTION OF THE LIVER
AND THE ETIOLOGY OF PROGRESSIVE
HEPATIC CIRRHOSIS.

Some time ago an editorial summary of recent investigations into the micrococcal origin of common cirrhosis of the liver, by ADAMI of Montreal, appeared in the JOURNAL. Since then ADAMI has continued to faithfully study the subject, and from a communication to the *British Medical Journal*, Oct. 22, 1898, it is seen that the results which he has obtained modify to a certain extent his earlier conclusions and throw a new light upon a hitherto but little recognized function of the liver, namely, the bactericidal. It will be recalled that he demonstrated the presence in cirrhotic livers of certain diplococci and peculiar degenerated bacterial forms. Subcultures from an organism isolated from a cirrhotic liver showed that it concerned an attenuated form or a variety of the colon bacillus.

ADAMI is not able, after weighing all the facts to be taken into consideration, to separate the micro-organisms of cirrhosis from the main group of colon bacilli. Inoculating broth cultures of the attenuated, as well as the ordinary form, into the circulation, he found that in twenty-four hours the liver cells were crowded with diplococcal organisms. They were present in greater numbers in the liver than in the spleen, kidneys, or other organs, and yet when cultures were made within a few hours after inoculation but few colonies were obtained from the liver, the cells of which were crowded with bacteria, whereas abundant growths resulted in the cultures made from

the spleen, heart's blood and kidney. In these early cases he found the bile to be sterile.

From these observations it is clear that the liver cells do not act merely as excretory agents for the bacilli, but have pronounced bactericidal properties. The bacilli or diplococci seen in the liver were clearly, if not dead, at least incapable of proliferating to any great extent outside the body. The diplococcal forms, as well as other peculiar bodies, are looked upon as a result of degenerative changes. In certain cultures outside of the body, ADAMI also found that the bacillus took on the form of diplococci of fair size; strings of spheric bodies surrounded by a common substance can also form. These bodies are most easily demonstrable when the bacillus is grown under conditions unfavorable for active proliferation.

ADAMI then examined sections from the livers of a large number of postmortems, in which there were no changes characteristic of cirrhosis, and he was greatly surprised to find that these livers also contained, with scarcely an exception, these shadows of the colon or allied bacilli and, furthermore, that some of the fine brown pigment commonly seen in apparently healthy liver cells is undoubtedly to a certain extent the result of destruction of colon bacilli or other organisms. Hence, he concludes that the colon bacilli in healthy individuals frequently find their way into the liver cells from the portal circulation, and that one of the functions of the liver is to destroy these organisms through the action of the liver cells.

In cirrhosis of the liver the number of bacillary remnants and corpses is much greater than in the healthy liver, and this fact must be considered as pointing to a more or less direct connection between the microbes and the cirrhotic process. The facts obtained from the study of Pictou cattle disease in which, as alluded to in our former editorial, there is a marked cirrhosis of the liver, also favors the relationship between the microbes and the cirrhosis. ADAMI has not yet been able, however, to produce cirrhotic changes in laboratory animals on simple inoculation of the colon bacillus, so that if there is any connection between the organisms found in the liver and the interstitial proliferation, there must be other factors at work. ADAMI suggests that when the liver cells are lowered in their vitality, as for instance by the use of alcohol, then the bacilli, finding their entrance into the liver in larger numbers than usual, perhaps on account of the existence of chronic inflammatory changes in the digestive tract, which is a very familiar feature in the clinical history of cirrhosis in man, may produce the progressive proliferative changes characteristic of cirrhosis of the liver. ADAMI has undertaken experiments in which he is employing cultures of the colon bacillus alternately with alcohol, for the purpose of showing whether or not this condition of pathogenic agents may throw any further light upon the cirrhosis problem.

Leaving out of consideration, for the time being, the bearing which ADAMI's observations have upon the cirrhosis problem, it would seem that a very important result of his faithful labors is the demonstration of the bactericidal function of the liver above alluded to. It will be recalled that FUTTERER of Chicago has recently published the results of certain investigations¹ which show that bacteria introduced into the general or portal circulation, are eliminated largely through the liver by way of the bile in an almost incredibly short time after their introduction. From his results it would appear that the liver exercised an excretory function principally, whereas from ADAMI's results the bactericidal properties of the liver cells were brought forward quite clearly. In FUTTERER's experiments the colon bacillus, however, was not used, and it may be it will be found that the bactericidal functions of the liver are concerned more particularly with ridding the organism of this microbe.

TYPHOID FEVER IN MILITARY CAMPS.

There is an undercurrent of belief among our older medical men that the mortality from disease during the War with Spain was not relatively so great as that from which our volunteer troops suffered during the Civil War, and this belief is very generally shown by the veterans of the Grand Army, who recall the rapidity with which the original strength of their regiments melted away under the hardships and exposures of life in camps long before they had an opportunity of coming in contact with the enemy. The letter published in our last issue from Deputy Surgeon-General SMART, gave a solid groundwork for this belief by defining very clearly the want of parallelism in the monthly lines of mortality in the two wars. Now that we have followed the labors of our army medical men in caring for the sick of the past few months, the figures which Dr. SMART presents from the old records have a deeper significance to us than they would have had prior to this recent experience.

We have all along had a realizing sense of the danger to which our troops would be exposed from the infection of typhoid fever. In our issue of June 4, when the public was viewing with alarm the possible ravages of yellow fever in the ranks of the volunteers, we took the position that the camp fever which was to be feared was typhoid and not yellow fever. The events of the succeeding months, both at Santiago and in the large camps in this country, have demonstrated the accuracy of our prognosis, which was the certain spread of the disease among the hastily raised and undisciplined regiments unless medical and line officers of every grade devoted themselves earnestly and intelligently to perfect the sanitary conditions of their camps. This was not done. In June and July typhoid fever appeared sporadically in certain of the

regiments in these large camps. In some instances the disease was recognized as having been imported from State camps and in others to have been due to infection from outside the regimental lines. One fact is prominent: that it was not the result of an infection of the general water-supply, because had it been so the outbreak would have been fulminant, as in the epidemic some years ago at Bethlehem, Pa., when its water-supply became infected. The care given to the water-supply of the camps by the Quartermaster's Department at the instance of Surgeon-General STERNBERG may therefore be credited with the preservation of the troops from such an epidemic attack. But in August the prevalence of the disease became so increased as to call for a removal of the causes. Investigation by qualified inspectors determined that the increased prevalence had its origin in the general infection of the camp sites from the sporadic cases which had occurred, this general infection having become possible owing to overcrowding in the camps and the neglect of sanitary precautions in the care of the sinks; and the charge against the ordinarily insignificant house-fly of being an active agent in the propagation of the disease appears to have been accepted by those who had most experience of the conditions. Removal from the infected sites was immediately recommended and adopted as the best means of lessening the prevalence and ultimately subduing the outbreak. In September a marked diminution in the number of cases was observed.

Up to this time it has not been possible to obtain any data for a comparison with the spread of this fever among the young men who volunteered in 1861, because reports have come slowly into the office of the Surgeon-General, owing to the difficulties encountered by volunteer surgeons in making out official papers. The published records show that from May, 1861, to May, 1862, in which period are included both the maximum of prevalence and the maximum of fatality of typhoid fever, there were 30,550 cases and 5171 deaths reported from an average strength of about 236,000 men or less than one-half of the 500,000 three-years' men then in the service. Among these cases are included those lighter febrile attacks which were recorded by the surgeons as simple or common continued fever, but which would now be regarded and reported as mild cases of typhoid fever. From the Surgeon-General of the Army we learn that up to September 30, 1898, there were reported 12,125 cases of typhoid fever, 640 of which were fatal, among commands aggregating about 167,000 men, or somewhat over 60 per cent. of the troops in service. Now if we calculate the number of cases and deaths which would have occurred in 167,000 men in five months if the rates of 1861-62 had prevailed in 1898, we would find that instead of having 12,125 cases, we would have had only 8308, and that instead of having only 640 deaths we would have had 1402 deaths. From this

¹ Medicine, 1897 and 1898.

we find that during the recent experience of our armies the prevalence of typhoid fever was greater by one-third and the deaths less by 55 per cent. than during the Civil War.

The fatality of typhoid fever, including the common continued cases aforesaid, during the first thirteen months of the Civil War was 1 in 6 cases or about 17 per cent. The fatality of the typhoid fever in our military camps and hospitals during the present year was 1 in 19 cases or a little over 5 per cent. This is certainly a most remarkable rate for typhoid fever, especially when consideration is given to the want of suitable medicines, food, nurses and shelter which, according to newspaper reports, characterized the service of the military hospitals—regimental, division and general. This low mortality rate is in itself sufficient to throw doubt upon all the general charges of neglect of the sick soldier and inadequate provision for his treatment. It is indeed so low as to leave a broad margin of doubt to overlap the reported cases and to suggest the inquiry whether every case reported as typhoid was in reality a case of that grave disease. We know that during epidemics of yellow fever, cases of remittent fever frequently increase the number of those reported as smitten by the prevailing disease. Something analogous may have taken place during the recent excitement concerning camp typhoid.

Our military brethren have learned much recently regarding the propagation of typhoid fever in the camps of newly raised troops. They have demonstrated the importance of strict discipline and military sanitation in the preservation of the strength of their commands. The typhoid epidemic of August last has been checked by radical measures involving the reorganization of practically all the troops in the service; but as the susceptibility of these troops to the typhoid infection has not been exhausted, the task of preserving them from such losses as were incurred during the Civil War yet remains before the Medical Department of the Army. Many months will have to elapse before we can gauge accurately the result of their efforts to protect the men from the infection of camp typhoid.

TIME AND MANNER OF THE ADMINISTRATION OF DRUGS.

Search for the causation of disease has so engrossed the attention of the medical profession that but little time is devoted to the proper manner of the restoration of the equilibrium to the normal. Surely to properly diagnose a case is not all of a physician's duty, for then the patient may die. What the patient desires most is to get well as quickly as possible. Those who practice irregular medicine have not been slow in learning this prejudice of the people, and have turned it into a financial gain to themselves.

Good-tasting medicine is a great catchpenny to homeopaths, for if it does no good it pleases the

parents and thereby diverts money from the hands of physicians to the pockets of the irregulars. This practice is common and is most appreciated by those physicians who live in cities. How often do we hear it said that the reason so-and-so were "converted" was because they did not like to take the bad-tasting medicine of the "old-school" doctors. Those who carry out this line of thought logically and naturally think: If the weak or good-tasting medicine of the homeopaths cures as many people as the other, then why take any medicine at all? And from these premises it would not be far to believe the tenets of Christian scientists, because, forsooth, it is a matter of faith anyway.

An art that is yet to be learned is the time for the administration of drugs. What good will it do a patient to give a highly nutritive diet, if asafetida, cod-liver oil, guaiac or quinin is to be given immediately before meals? What good will a saline purgative do when given immediately after a meal? If the patient is awakened during the night to take nourishment and medicine at the same time, what good will he derive from either? Our sense of taste and smell must at least serve some purpose, for our appetite craves for that which is good. In disease, the appetite is held in abeyance, perverted and most uncertain. Drugs do not furnish nourishment; they simply act upon the force generated by the nourishment taken. Then why destroy this force? There then must be a proper time, and there must be a proper manner of giving medicine.

Elegance in pharmacy should be encouraged. The art of prescription-writing should be learned. In this respect we should copy after the French, who are noted for their elegance in pharmacy. Gelatin capsules serve a most valuable purpose to the regular physician; for unpalatable drugs may thus be taken without being tasted. Compressed triturates should be received with great joy, for they demonstrate the energy and enterprise of the "old school" doctors. All drugs, however, can not be put in tablet form. Some drugs are volatile and others hygroscopic; therefore solutions must always have a place. The art of disguising the taste of unpalatable drugs so that the patient can or *will* take them is one not easily acquired by the profession, because it is largely governed by manufacturers of patent medicines. With the child, a solution of magnesium sulphate or an emulsion of castor oil causes disobedience, and frequently the mother will not give them. Some children will vomit when given too sweet drugs, while the adult loses his appetite. Half an ounce of myrrh to a four-ounce mixture is usually sufficient.

Alcoholic extracts, such as cannabis indica, cubebs, or eucalyptus, precipitate on the addition of water, and therefore should be given in capsules. Solutions of quinin, bromids, and prescriptions containing fluid extracts may be rendered palatable by the addition of

a syrup containing aromatics, such as the elixir curacao of the National Formulary. Oleorins are unsavory and frequently render a patient most rebellious. The taste of copaiba, cubebs and sandalwood remains in the mouth for hours. There is a little art required in dispensing these substances in gelatin capsules, as follows: Place the oil in the capsule by means of a pipette and seal with an alcoholic-ethereal solution of balsam of tolu. Rochelle or epsom salts are very soluble and should be dissolved in a small quantity of water and taken, and subsequently a large amount of water given if desired. Guaiac has come down to us from former times as a valuable remedy in rheumatism, gout, lithemia, etc., but there are few textbooks which tell of its proper administration. Here again the manufacturers of patent medicines pervert legitimate pharmacy from its proper channels, because it is easier to give something else than to combine the guaiac in lozenge form by means of the confection of rose and flavored with oil of lemon and cloves. In cod liver oil we have one of the best known tonics, yet how often do we find that it can not be borne by the patient. To disguise its taste and render it palatable frequently baffles the physician, so that if one of the proprietary emulsions is not used the remedy may be abandoned. Cod liver oil that has become rancid can never be disguised, and will in nearly every case disturb the stomach, so its character should always be under the surveillance of the attending physician. In most cases an emulsion that is borne well can be prepared by taking the yolks of three eggs, triturating in a mortar for *at least* fifteen minutes, and then adding the oil teaspoonful by teaspoonful until the whole has been incorporated. The yolks of three eggs will suffice for a quart of finished emulsion. Probably the best ingredient to disguise its taste is bitter almond water, usually an ounce being required for a quart of emulsion.

While these few remedies are not all that might receive attention, it is hoped that a few hints may be thrown out which will benefit the general practitioner and keep legitimate pharmacy within proper bounds.

THE DANGER OF CHLOROFORM ANESTHESIA IN OPERATIONS UPON THE THROAT.

It has become the habit of many surgeons, even among those opposed to the drug, to administer chloroform in operations upon children requiring an anesthetic. The ease of administration, the quickness with which the child becomes unconscious, the small quantity of chloroform necessary to procure unconsciousness, the rapidity with which they emerge from under the influence of the drug, the inconsequent after-effect, have all held us to this view. Of the surgeons who have made diseases of the throat their chief study, many no doubt have been worried not infrequently over the dangerous symptoms developed by the child during the administration of chloroform,

even if they have not been so unfortunate as to have had a fatal accident. Especially have these alarming symptoms been noted in children afflicted with enlarged tonsils or adenoid vegetations in the vault of the pharynx. The writer has given chloroform to a fair number of children suffering with adenoids, but never without great anxiety and with more than usual caution, so badly do these children act. Probably not one out of ten takes the anesthetic in a manner that might be called normal. The writer has noticed often at the very marked outset, pallor of the face and a rapidly progressing diminishing frequency of the pulse-rate, so much so, indeed, that it sometimes seems to the palpating finger that the heart is never to beat again; and this in spite of the fact that the chloroform is given drop by drop and very slowly. The pupils remain well contracted. If the anesthetic is continued serious symptoms usually develop; if discontinued, as the patient comes from under, the pulse gradually regains its normal rate and the pallor disappears. It may be that this same misfortune will again happen if the drug is readministered. Frequently the operator becomes desperate and, disregarding the old law of never beginning an operation when chloroform is the anesthetic, before the patient is completely under, proceeds with curettement, adding to the danger of the child.

HINKEL, in the *New York Medical Journal* for October 29, reports a death after the operation for adenoids with chloroform as the anesthetic, and has collected from the literature seventeen more cases during the past five years. His case was an anemic boy of six years with a lymphatic constitution. The anesthetic had been given by a skilled man, one who had had experience in just this class of cases and was consequently more than usually careful. The operation had been successfully terminated, "when suddenly the boy gave a few hurried shallow gasps and respiration ceased. The pulse had disappeared and no cardiac impulse could be felt or heard; the pupils were dilated." Everything was done that could be done to restore the heart and respiration, but without success.

The discovery of eighteen authentic fatalities (and who knows how many other deaths have occurred from the same cause, not reported?) is a most valuable contribution to laryngology; showing, as it does, that the administration of chloroform to this class of cases is dangerous and should be entered into with the greatest care and with all appliances for restoration close at hand. Two of the eighteen died before the operation commenced; this, combined with the fact above mentioned, that most of the patients take the drug badly from the start, would seem to lead to the belief that there is some condition of the constitution that makes it intolerant of chloroform vapor even in small doses. HINKEL, who has looked up the literature of the subject very closely, makes the following

statement compiled from the writings of KOLISKO, PALTAUF, and others: "It has been found postmortem in a number of cases of sudden death from slight causes that there was present hypertrophy of the lymphoid tissue throughout the body, including the tonsils, the lymphoid structure at the root of the tongue and the nasopharyngeal adenoids for which we so frequently operate. The thymus gland was persistent and often very large, and the intestinal follicles were markedly hypertrophied. In addition there were frequently present a dilated heart not dependent on valvular lesions, and at times a narrowing of the aorta with small size of the peripheral vessels. This condition, which has been called *habitus lymphaticus*, was found among others in a number of cases of death during chloroform administration. People so constituted seem to have little power of resistance to comparatively slight shocks. Nevertheless they may be of robust physique, though usually there are evidences of developmental retardation." All throat specialists are familiar with this very common patient. In addition to the adenoids, there is usually hypertrophy of the faucial tonsil; the glands of the neck are readily palpable; the complexion, though usually exquisite, may be marred by excoriations around the nostrils, the result of chronic nasal discharge; there is frequently an eczematous eruption behind the ears; blepharitis marginalis is by no means uncommon.

Another point of considerable importance has been worked out by HINKEL: that during the last five years, the period covered by his eighteen cases of chloroform death, but six deaths have occurred from the operation itself, and all these as a result of hemorrhage, usually secondary, almost always in patients the subjects of hemophilia.

The practical lesson we must learn from this careful study is that patients of the so-called lymphatic temperament should not as a rule be anesthetized with chloroform for any operation; and that in operations upon the throat this rule becomes imperative.

THE STRUGGLE FOR EXISTENCE BETWEEN THE HUMAN ORGANS.

One of the problems actively discussed in biology is the origin of the atrophies and hypertrophies which mark both evolution and its reverse phase, degeneracy. The fact was early recognized by biologists that man is a compound animal in whom certain structures are endowed with their own nervous system, which is under control of the central nervous system. As has been pointed out by E. S. TALBOT ("Degeneracy: Its Scope, Causes and Effects"), every vertebrate is an aggregate whose internal actions are adapted to counterbalance its external actions. Hence preservation of its movable equilibrium depends upon its development and the proper number of these actions. The movable equilibrium may be ruined when one of these actions is too great or too small, and through

deficiency or need of some organic or inorganic cause in its surroundings. Every individual can adapt itself to these changeable influences in two ways: either directly, or by producing new individuals who will take the place of those in whom the equilibrium has been destroyed. Therefore, there exist forces preservative and destructive of the race. Since it is impossible that these two varieties of force should counterbalance each other, it is necessary that the equilibrium should re-establish itself in an orderly way. As there are two preservative forces of every animal group—the impulse of every individual to self-preservation and the impulse to the production of other individuals—these faculties must vary in an inverse ratio; the former must diminish when the second augments. Degeneration constitutes a process of disintegration. Hence if the term "individuation" be applied to all the processes which complete and sustain the life of the individual and that of generation, to those which aid the formation and development of new individuals, individuation and generation are necessarily antagonistic, as HERBERT SPENCER has shown.

Vertebrate embryos, which are all of a common type at their origin, assume, as VON BAER has demonstrated successively, a number of common forms before definitely differentiating. Supernumerary organs exist, as DARESTE points out, in these common forms at one phase of embryonic life. This community of embryonic types and this last fact, explains repetition of teratologic types in vertebrates. This community of origin, moreover, indicates that the higher vertebrate embryo contains in essence the organs and potentialities of all the lower vertebrates, and that, under the influence of heredity or accidental defect, an organ or structure or function constant in a species may be lacking in an individual without the necessity of explaining the immediate effects by distant atavism.

Varying conditions must stimulate these embryologic potentialities at the expense of the later acquired and more typic human organs. The COHNHEIM theory of cancer, for example, is an illustration of the application of this principle. From this results a struggle for existence on the part of organs and structures which, early observed by ARISTOTLE, GOETHE and ST. HILAIRE, was forcibly shown by ROUX two decades ago. ROUX ("Der Kampf der Theile in Organismus"), while also admitting determination by heredity, points out that there are surrounding forces always necessary, not simply the condition of activity by an essential element of the final product. He thus harmonizes the extremes of WEISSMANN and GOETHE by the fact of an internal or physiologic struggle for existence between the organs, the cells and the protoplasmic molecules of the organism. This unsimilarity of parts makes it impossible to establish laws of heredity which shall govern details of function as to the last cell or molecule, as in any army, the commander-in-chief does not give special orders beforehand affecting every

private in the ranks. There must be a possibility of adaptation to surroundings, especially in details which, too, are more easily changed than events on a larger scale.

How is this freedom of organs and of adaptation obtained? The principle that lies back of all development of tissues and organs is over-compensation of what is used, a quality which permits self-regulation and is really a necessary pre-condition of life. Living matter, unlike inorganic matter, presents an external continuity in spite of change of conditions. To effect this, assimilation must always be in excess (over-compensation) for if less than consumption, the organism comes to an end of itself. If equal conditions result, change and nourishment will fail or injurious events will cause destruction. Continuance can only be assured when more is assimilated than is consumed. Fire, for example, assimilates more than it uses, i.e., it always has energy left over to kindle new material. Fire would (like life) become eternal if it did not use up material quicker than other processes can make them. In the same way organisms assimilate more than they can consume, but they do not turn all they use to assimilation; energy remains over by which the process performs something. This work-product controls the excessive assimilation which otherwise would come to an end by not having sufficient material to assimilate. The more complex processes of life are, hence, essentially, as COLIN A. SCOTT remarks (*American Psychological Journal*, 1888), a radiation of assimilation which, although not identical with combustion, is similar to it; the load which it carries favoring its continuity. This radiation, load or work-product becomes directed by natural selection to keep up a supply of food primarily by moving the assimilating mass. Performance of function over and above assimilation is just as much a condition of continuous assimilation as assimilation is of performance. On the other hand, there comes to be an inverse relationship between growth and production (within limits), and capacities result which, although they use up material, do not in themselves increase assimilation. The course of development consists in properly directing this work-product. This so far represents merely a continuous productibility of function in connection with assimilation. But a productibility which is stored up and discharged by an outer stimulus of environment will be much more economic and will give rise to what we find as reflex excitability. When this reflex work-product dominates, according to circumstances, function will sometimes be greater and sometimes less. If, under these conditions, assimilation keeps on continuously, there must sometimes be an overplus, sometimes a balance and sometimes an excessive function, death, and thus elimination. To avoid this last, it is necessary that assimilation should depend upon use or upon a stimulus which use calls forth.

From the psychic side stimulus is recognized as hunger.

This kind of process, where stimulus is an indispensable factor, is more special and limited than the more general process of assimilation plus movement, etc., but has characteristics which favor it greatly in the struggle for existence. Connected with the most complete self-regulation of functioning is the greatest saving of material. While those parts, according to their use, are strengthened and grow, the unused degenerate, and the material for their substance is saved. This kind of process unites the greatest economy with the highest functioning of the whole, but at the cost of the independence of the parts. Senescence becomes thus a result in differentiation in which the parts exist merely on account of the function which they perform for the whole. The senescing organs wither up like State officials after pensioning, and may even descend in this condition from generation to generation, a fact which often allows a fresh start in development. During the course of a lifetime the organism moves from a more general, more easily impressible condition to one more perfectly mechanized. Through a long period it becomes, through the continuous working of a given stimulus, more completely adapted to itself and also more differentiated, and thereby more stable, so that an always increasing opposition is formed to the additional development of new forms and characteristics. This principle, known as the law of economy of growth, governs the relations of the organs to each other, the operation of the principle whereby one structure is sacrificed for the development of another. This, as already stated, was pointed out first by ARISTOTLE, as OSBORN has shown ("From the Greeks to Darwin"). GOETHE first clearly enunciated it in 1807, and it was urged with additional emphasis by ST. HILAIRE in 1818. In a general way, therefore, as DOHRN has shown, this principle holds good of man not only as an organic unit, but as a compound organism.

Degeneracy, according to RAY LANKESTER, is a gradual change of structures by which the organism becomes adapted to less varied and less complex conditions of life. The opposite progressive process of elaboration is a gradual change of structure by which the organism becomes adapted to more varied and complex conditions of existence. In elaboration, there is a new expression of form corresponding to new perfection of work in the animal machine. In degeneracy, there is a suppression of form corresponding to the cessation of work. Elaboration of some one organ may be a necessary accompaniment of degeneracy in all the others. This is very generally the case. Only when the total result of the elaboration of some organs and the degeneracy of others, is such as to leave the whole mass in a lower condition, that is fitted to less complex action and reaction in regard

to its surroundings than is the type, can the individual be regarded as an instance of degeneracy. These degeneracies appear at varying periods, since struggles for existence on the part of the different organs and systems of the body are most ardent during periods of body evolution and involution. During fetal life, during the first dentition, during the second dentition (often as late as the thirteenth year), during puberty and adolescence (14 to 25 years), during the climacteric (40 to 60 years), when uterine involution occurs in woman and prostate involution to man, and finally, during senility (60 years and upward), during all these periods degeneracy may be shown by mental or physical defect, a congenital tendency to which has remained dormant until the period of stress. These defects may be such biochemic alterations (undemonstrable by existing methods) as lead to diminished inhibitory power or other altered function or to secondary pathologic or teratologic change of decidedly demonstrable nature. Organs and structures checked at a certain phase of development may pursue a course of development differing from that indicated in man, but further outlined in other vertebrates.

Are the results of this contest for existence always malign? According to the accepted principle of natural selection this should not be so, since the struggle creates variations of value or not according to the environment.

As HARRIET ALEXANDER points out (*Medicine*, 1896), since degeneracy is a process of evolution, leading to alteration of form because of cessation of inhibitions in certain directions resultant on diminished work, it logically follows that since diminished functioning precedes change of structure, increased functioning must check the change of structure in its biochemic stage. Nay, more, it is evident that the structural elaboration due to degeneracy may be retained while the degenerate structures resume their higher functions. Hence the degenerate race ranks higher in evolution because of the utilization of the beneficial variations due to degeneracy. The influence of this principle is increased by the fact that the majority of the children of degenerates inherit a tendency to degeneracy rather than degeneracy itself. This is also the view of HUXLEY, who expresses the opinion that genius is innate capacity of any kind above the average mental level. From a biologic point of view a genius among men stands in the same position as a "sport" among animals and plants, and is a product of that variability which is the postulate of selection, both natural and artificial. On the general ground that a strong and, therefore, markedly abnormal variety is, *ipse facto*, not likely to be so well in harmony with existing conditions as the normal standard (which has been brought to what it is largely by the operation of those conditions), a large proportion of "genius sports" are likely to come to grief physically and socially, and the intensity of feeling which is one

of the conditions of genius, is especially liable to run into insanity. This position of HUXLEY contains the principle which has become of late years so dominant in researches as to the origin of genius. In newspaper science, the theory of the degeneracy origin of genius is credited to NORDAU's investigations. This newspaper claim for NORDAU (repudiated by himself) is supported even by medical journalists. The editor of the *Medical Record* gives the following rather emphatic endorsement of the newspaper theory as to genius:

"MAX NORDAU's startling theory that genius is only a form of degeneracy, although not accepted in its entirety, is yet regarded by many as worthy of some consideration." With all his newspaper medical lore, or perhaps because of it, the editor of the *Record* exhibits an astonishing forgetfulness as to the origin and antiquity of the theory of genius being a degeneracy.

This theory is a very old favorite with mediocre intellects. As KIERNAN has shown (*Alienist and Neurologist*, 1892), this doctrine, early in the history of the race, obtained dominance through a natural evolution of arts, sciences and religions from fetichism. Phenomena manifested by fetich priests (of the SHAMAN type) so closely resembled epileptic insanity in its frenzies and visions, that the two states were long regarded as identical, whence the term *morbus sacer*. The supernatural influences, which in current belief underlie epilepsy, were at the outset malign or benign as they were offended or placated. They became benign, and the insane were under special protection of a deity, as in Mussulman countries. Later still, the demon possessions theory gained dominance and at length the demon sank into the disease. Throughout all this evolution the belief in an inherent affinity between insanity and genius persisted. In ARISTOTLE'S day the disease notion was becoming dominant, yet he says that under the influence of head congestion persons sometimes become prophets, sybils, and poets. Thus, MARK, the Syracusan, was a pretty fair poet during a maniac attack, but could not compose when sane. Men illustrious in poetry, arts and statesmanship are often insane like AJAX or misanthropic like BELLEROPHON. Even in a recent epoch similar dispositions are evident in PLATO, SOCRATES, EMPEDOCLES and many others; above all, the poets. According to PLATO "Delirium is by no means evil, but when it comes by gift of the gods a very great credit. In delirium the sybils of DELPHI and DODONA were of great service to Greece, but when of cold blood were of little or no value. Frequently, when the gods afflicted men with epidemics, a sacred delirium inspired some men with a remedy for these. The muses excite some souls to delirium, to glory with poetry heroes, or to instruct future generations."

DEMOCRITUS, whose biologic [researches are well-

known, was also of opinion that genius was associated with insanity when manifested in poetry. HORACE compressed the sentiment of his day, as to genius, into lines later paraphrased by DRYDEN:

Great wit to madness nearly is allied,
And thin partitions do their bounds divide.

This Horatian doctrine long had wide-spread vogue among Philistinish mediocrities (from envy of any superiority) and among morally defective geniuses from a desire to excuse faults and vices.

The superficial resemblances which the miso-nism of mediocrity found to exist between the emotional enthusiasm of the intellectual stir of the poet and the opposite state of hypomaniac emotional exaltation, as well as that seeming to exist between the rapid finely graded logic of the sage and disjointed saltatorial reasoning of the paranoiac, may have helped to fix more strongly the doctrine on the minds of these who accepted it. SENECA expresses the opinion that no genius exists without an admixture of madness. MONTAIGNE and BURTON (the "Anatomy of Melancholy") advance similar views. SWIFT seriously makes, with grim irony ("Tale of a Tub," dissertation on madness), the proposal that the world shall choose its geniuses from Bedlam. PASCAL accepts HORACE'S view anent the kinship of genius and insanity. According to FELIX PLATER ("Observations in Hom. Affect., 1641), madness and genius are very near, an opinion which was later reiterated by DIDEROT ("Dictionnaire Encyclopedique"). In the late eighteenth and early nineteenth century a certain amount of reaction occurred against the doctrine. TISSOT, the great psychologist, one of the earliest writers to point out the effect of the psychic disturbances from fear and shock in the production of *delirium acutum nervosum*, as the older surgeons called post-operative insanity, wrote a work ("Mala-dies des Hommes de Lettres," 1796) intended to prove that most of the afflictions of literary genius were occupation disorders, not inherited degeneracies.

With the impetus given the evolution doctrine during the first half of the nineteenth century, the degeneracy phase of genius was again strongly urged. Mr. MADDEN began the work "Infirmities of Genius" (1833) later supplemented by the magnificent epoch-making treatise of MOREAU DE TOURS, "La Psychologie Morbide" (1859) on the subject. In many respects this work, considered from the standpoint of logical analysis and arrangement of facts, surpasses most later treatises on the subject. It certainly compares favorably with MAUDSLEY'S vaticinations on genius, with the researches of J. A. SCHILLING (*Psychiatrisches Briefe*, 1863), with the work of HAGEN ("Verwandschaft des Genie mit dem Irsinn," 1877), with JURGEN-MEYERS' researches (*Zeitschrift f. Volker-Psychologie*, 1879), with LOMBROSO'S work ("L'Uomo de Genie," 1883), with that of RADE-

STOCK ("Genie und Wahnsinn," 1884), with that of TEBALDI (*Ragione e Pazzia*, 1884), with the researches of TARNOWSKI and TCHUKINOV, who translated into Russian, with additions, LOMBROSO'S work in 1885, and with the work of NISBET ("Insanity of Genius," 1892). NORDAU, as he admits, merely popularized pessimistically the views LOMBROSO expanded from MOREAU DE TOURS, who had a quarter of a century previously characterized genius as a neurosis. According to LOMBROSO it is a degenerative epileptoid neurosis.

Notwithstanding the *Medical Record's* learned opinion, the degeneracy theory of genius has not as yet reached that stage where it fulfills scientific requirements, since it not only does not as yet explain all the facts, but it fails to exclude all other explanations.

However, not even those who, like KIERNAN, claim that where neuropathy and genius coexist (*Alienist and Neurologist*, 1887) the genius is an expression of healthy atavism, will deny that the struggle for existence between organs and structures, already outlined, may produce variations which, when the organism secures the balance between its warring structures, must elevate the race in the scale of evolution. The principle thus enunciated lights up, as HARRIET ALEXANDER remarks, the gloom of the ordinary pessimistic view of degeneracy with a well-defined hope that the functionally defective neurons of the degenerate may be trained

Till within
The twilight mazes of his brain
(Like embryos within the womb)
Thought pushes feelers through the gloom.

It also points out optimistic possibilities of that future when man shall have learned to adjust the struggle for existence between his structures for the greatest benefit of the organism as a whole.

CORRESPONDENCE.

The Commission Evil.

NEW YORK, Nov. 14, 1898.

To the Editor:—In the JOURNAL of Nov. 13, 1898, I find an editorial under the caption of "The Commission Evil" which reads almost like a slander upon the profession, and which leads me to ask if the editor actually has knowledge of specific instances in which a commission or rebate has been paid by the general practitioner to the specialist?

My own work is almost wholly with physicians, and among the hundreds with whom I come in contact not one has ever intimated that he would like to have a commission or rebate. Sometimes when I have done work for a poor patient whose friends have collected a small fee for me and none at all for the family physician, who has much work to do for the patient, I have insisted that the physician should take a part of the fee, and even in such cases have usually found him unwilling to take any part thereof. Possibly the report that specialists claim commissions has come from some one who feared that he was not getting his share of work because he did not give commissions, but the acquaintances of such a man could probably in-

form him of the real reason why he had failed to engage the confidence of physicians. Not long ago a truss-maker offered a 10 per cent. commission on all cases referred to him, and all my cases for trusses have since then been directed to go elsewhere. Every responsible physician knows how patients trust him and he selects with great care the specialist who is to do work for any of his clientele. He must be instinctively repelled by the idea of receiving a commission for doing the right thing by a patient who has put confidence in him.

Physicians in my circle of acquaintance present two well-marked attitudes. In one class the physician persuades me to do work for small fees, hoping thereby to gain personal prestige with the patient. In the other class the physician says, "I want to be fair to you and to my patient. My patient can not pay you \$5000 for his operation without depriving himself a good deal, but he can pay you \$2500. A third class in which the physician asks for or would accept a commission is not met with in my practice at all, and I believe that my practice is representative, and that other surgeons who are held to be responsible men will give precisely the same testimony.

ROBERT T. MORRIS, M.D.

"A Physiologic Question of Practical Importance."

OWATONNA, MINN., Nov. 18, 1898.

To the Editor:—I was interested in your editorial in the JOURNAL of November 12, under the above caption, but wish to correct an erroneous impression you have conveyed to your readers in it.

The fact is, that the official investigation in the Tryon case showed that the Admiral was so thoroughly under the influence of alcoholic intoxicants as to render him incompetent for the performance of almost any intelligent function.

There is but little doubt that many of the cases to which you refer originate in the same manner, though perhaps not from this identical cause. It is well known that there are various drugs which produce such results, and there is but little doubt that the excessive use of tea, coffee and tobacco may be responsible. However, the fact still remains that we often do have the phenomena to which you refer resulting from a perversion of some one or more of the cerebral or nervous functions. I think the trouble is fully as likely to be in some of the special senses as anywhere, though doubtless it is often located in some of the higher cerebral centers which connect us with our environment. It is certainly a fascinating study, though one in which the omnipresent microbe may for once probably be eliminated, and one which should yield profitable results to him who follows it.

Very truly yours,

THEO. L. HATCH, M.D.

Vital Statistics of the War.

CAMDEN, N. J., Nov. 16, 1898.

To the Editor:—Dr. Charles Smart of the U. S. A., in a letter directed to you, of the date of October 22, complains of an editorial which appeared in the *Philadelphia Medical Journal* relative to the mortality in the Spanish war, and causes of the mortality.

What he says is all very well for the most part; but will he explain why so many soldiers not exposed to the hardships of war, but quartered in a country rich and resourceful in every way, died of disease. When we consider that these same soldiers had all undergone strict physical examination and been pronounced of excellent resisting power, the mortality among them seems to indicate gross incapacity somewhere.

Suppose that during the Civil War proportionately as large a number of soldiers had been isolated from the scene of actual warfare and that the same percentage of deaths had occurred among them, would not the mortality have seemed frightful?

Respectfully yours,

J. F. WALSH, M.D.

PUBLIC HEALTH.

The National Quarantine Convention at Memphis. Pursuant to call, the National quarantine convention assembled in Germania Hall, Memphis, Tenn., November 17. Chairman J. S. Menken of the committee on organization called the meeting to order. After addresses of welcome by Mayor J. J. Williams and Mr. Menken, Gen. Luke E. Wright was unanimously chosen as permanent chairman. He spoke of the objects of the convention and the benefit to be derived from National control of quarantine matters. The organization was completed by the election of Mr. Phil. A. Ruek of Senatobia, Miss., as secretary, and Mr. Fred Orgill of Memphis as assistant secretary. The balance of the morning session was consumed in the discussion regarding the equitable representation of the States and in the completion of the different committees. The afternoon session was devoted to the reading of various resolutions presented for consideration. By order they were respectively referred to the committee on resolutions without debate.

At the evening session the first paper was by Dr. John B. Hamilton of Chicago. He prefaced his remarks by stating that it was fortunate for this convention to be held in Memphis, because it was twenty years ago in the throes of agony from a fever epidemic, while it was, on account of its present excellent sanitary conditions, free from this and other diseases and therefore an object lesson to show the results of applied sanitary science.

He passed the origin of yellow fever with the statement that it was exotic, a living organism, but whether vegetable or animal it mattered not. As the fever organism traveled only by the ordinary vehicles of conveyance, its spread could be stopped by stopping these vehicles, as was done during the Civil War by blockade. Its spread from Brownsville, Texas, was prevented during 1883, while without these precautions it spread greatly in Mexico. In the same year an epidemic of fever was prevented from spreading from Warrington to Pensacola, Fla., only two miles distant. Proper measures also prevented its spread from Decatur, Ala., in 1888. Mentioning other similar instances he said that whenever commerce had been bound and epidemics had spread since 1891 it was due to maladministration, in failure to apply rules of sanitary science.

In regard to panic and its prevention, the only way he knew of preventing panic was to teach the people that the death-rate from yellow fever had been greatly reduced; that tuberculosis annually destroyed one hundred times as many lives; and that typhoid fever had a higher and a greater death-rate than yellow fever. With proper sanitation and isolation of the first case, he said, there was little chance for it to spread in cities.

Today, more than at any previous period in the history of this country, America is in a position to press the matter of sanitation in cities not formerly under our control, from which have emanated, for the last two centuries, a steady stream of death dealing microbes. The duty of the government is clear, that, at whatever cost, the foul plague spot which the providence of God has placed in our hands, shall be made clean and healthful. These beautiful isles of the sea, so favorably situated by nature, should be purged of contamination.

Already we see the admirable result of the cleansing of Santiago, and in that city, for the last seventy days, there has not been a single case of yellow fever, a condition which that city has not been able to report for a hundred years, so far as known. Our sister republic of Mexico, which now has an excellent national board of health, has, in view of the probable improvements about to take place in the islands of Cuba and Porto Rico, undertaken the sanitary regeneration of Vera Cruz, hitherto almost continuously infected with yellow fever for a period of over three hundred years. Shall we not take into consideration this bright outlook as to exemption from exotics, in discussing plans for the sanitary future of the United States?

I believe all have arrived at the conclusion that the present condition of things in this country is unsatisfactory, and that the situation has narrowed down to the presentation of two bills now pending in congress—one known as the Caffery Bill, and the other the Spooner Bill, which has been adopted by the AMERICAN MEDICAL ASSOCIATION and the American Public Health Association. The Caffery Bill, which has incorporated many of the features of the law of 1890, which was formerly superseded by the law of 1893, but in addition contains drastic clauses singularly inappropriate for the purposes of a free country, has been passed upon adversely by the sanitary bodies of this country, but its advo-

cates continue to contemptuously flaunt it in the faces and eyes of all of a public that wants none of it. The central idea of the Caffery Bill is force, power and control, not co-operation. Besides that it is the narrow one idea of quarantine, no great system of general hygiene is provided. On the other hand, contrast the broad, wise provisions of the Spooner Bill, framed after seven years of labor by professional committees of the American Medical and American Public Health Associations. The New York Board of Trade and Transportation, through a quarantine committee, spent many months by correspondence, by hearings and otherwise, in endeavoring to arrive at a conclusion in regard to this matter, and their recommendation is in favor of "legislation which shall organize in the United States a national system of coast and interstate disinfection."

"We use the word 'disinfection' as distinguished from 'quarantine,'" said Mr. Frank S. Gardiner, secretary of the board, when questioned, "because we are led to believe that with the adoption of a proper and general system of sanitation and disinfection throughout the country, guided and controlled by one general head in thorough harmony and sympathy with every local State board, every such board can be brought in touch and co-operation with every other local and State board, and what we have hitherto known as quarantine will practically disappear as being unnecessary, barbarous and obsolete."

The question before this convention is, will you recommend to congress the adoption of the AMERICAN MEDICAL ASSOCIATION Bill, providing for general sanitation, as well as quarantine, which provides for full co-operation with every State Board of Health, and through this full local representation with its executive officer elected by this representative council, or will you rather choose the Caffery Bill, devoted to the single subject of quarantine, more suitable for the empire of the czar or of the sultan than that of free America? I can foreshadow your choice.

Dr. S. D. Robbins, acting asst. surgeon, M.H.S., Vicksburg, Miss., in the paper which he read, strongly advocated the annexation of Cuba as probably the best way to deal with the question. He thought the government ought to take charge of Cuba and thoroughly renovate the island.

Dr. F. M. Rogers read a paper in which he traced the history of the fever from early times on down to the present time, and he went far into the details of a correct diagnosis and treatment of the disease. He concluded by advocating national control of quarantine matters.

The convention then adjourned until 9 o'clock November 17.

The second day's session was commenced with the reading of the paper of Dr. H. B. Horlbeck.

I unhesitatingly and without doubt express the conviction that the national laws as to quarantine that may be enacted by the Congress of the United States should be placed for execution in the hands of a separate and distinct representative bureau of health, to be organized at the seat of government at Washington.

Laws and regulations and rules framed under this organization should have the hearty co-operation of the people of the different States.

The laws of health in all the communities of these United States are practically expected to be enforced under the guidance of the members of the medical profession of such places.

The matter of the delegation of the conduct of national sanitation, quarantine and hygiene has engaged the close attention of the medical fraternity for a number of years in the recent past, culminating about eight years since in a distinct and decided act by the AMERICAN MEDICAL ASSOCIATION of the United States.

The AMERICAN MEDICAL ASSOCIATION possesses a membership of nearly ten thousand medical men, a roll of membership characterized by aspirations of the noblest endeavors that actuate mankind, and fulfilled by untiring and unselfish devotion. The committee of the AMERICAN MEDICAL ASSOCIATION appointed by them for this purpose, has been carrying out the wishes of that body in using every possible effort to have Congress enact a law creating a commission for the protection of the general health of the United States. The American Public Health Association, comprised of the members whose daily occupation is the practical solving of questions of hygiene in their respective States and municipalities, has spoken with no uncertain method in confirming the action of the AMERICAN MEDICAL ASSOCIATION. Thus we have the largest distinct sanitary body in the world and the largest medical association (far outnumbering any other organization of a similar character) in this country, who have given serious thought to these vital and all-absorbing questions, in an overwhelming majority expressing their judgment that all matters pertaining

to the national issues of health should be placed in the control of a representative commission, who shall organize a working bureau or department of health—a bureau in which every State should be represented.

These matters have been before the country for many years—the present systems have been unsatisfactory in their results.

Year after year, not only yellow fever but other contagious or infectious diseases are spread abroad between and among our States. The Marine-Hospital Service should confine its work and labore to the welfare of the sick sailors or seamen of the merchant marine of the United States. It was never entertained when this service was organized that the internal or external quarantine should be placed under its control. Nor is it proper that it should remain there any longer than a proper representative bureau can be organized for the purpose.

It is my conviction that as far as is possible the care of the health interests of each municipality and State should be under their respective boards of health, and it is my further conviction that all interstate matters of health quarantine, sanitation and hygiene should be under the control of a national bureau organized as above indicated.

The powers now granted by the quarantine act of Congress, passed and approved Feb. 15, 1893, are today most full and sweeping. With a strong, well-equipped and vigorous administration they would seem entirely sufficient. This law gives to the President the fullest powers possible to be granted, and no other power, marine hospital or national board should have more. This law gives power to the Secretary of the Treasury (that is, practically, the Marine Hospital Service) to make additional rules and regulations beyond the rules and regulations of States and municipalities that may be necessary, and on the failure of these States and municipalities to execute the additional rules and regulations, to carry them out, to enforce them. Why should an additional law be enacted, giving supreme and arbitrary power to the Marine-Hospital Service to force any and every community to carry out their mandates as to certification of persons or merchandise, under penalty of the hated and degrading stripe and ruinous penalty? When dealing with the organized municipalities of the United States, education and not force should be the compelling power. Men resort to extreme measures of the shotgun under great pressure of concealed peril. An enlightened and able organization, showing capacity for protection, would cause the rude interference of the shotgun to vanish as the melting snowflake in the flowing river.

The opportunity presents itself to this convention, composed of enlightened citizens representing not only the legally constituted guardians of the public health, but also the representatives of the various interests of many communities and States, to place upon record their demand upon Congress that they should organize a national bureau of health—to whom not alone the matters of national quarantine (which at best is an arbitrary necessity, only to be used under extreme occasion) should be given, but to whom the immense and all pervading questions affecting every home and homestead in the land should be referred for instruction and assistance when required as to betterment.

Scarlet fever, diphtheria, typhoid fever and the great white plague, consumption, year by year and month by month and day by day claim their tens and hundreds of thousands of victims. Of many, we have mentioned these few preventable diseases, which would be looked on with horror except for their constant and daily presence.

The duty and province of a bureau of health would be to enlighten the nation in all its walks, among the mighty and among the lowly; to prevent these diseases; to spread information by widely-circulated publications of the dangers from improper food and drink and surroundings; to gather information from all progressive and enlightened foreign lands, and to verify and develop all possible knowledge and give it to the country; to organize a biologic laboratory, where the problems of the dangers to life and well-being and happiness may be studied and the results made known, to collect vital statistics; to learn what places are unhealthy, and to say why they are not suitable for human habitation; to keep disease out of the country, and when it passes the confines to hinder its progress.

What an example England gives us! Quarantine is hardly known, but enlightened sanitation is practiced. Disease is prevented.

There is not a home in these States that can not be bettered, however well appointed it may be, and knowledge and information should be continually furnished for the guidance of the people by weekly bulletins that should be widely distributed.

For these and many other duties a national bureau of health should be established and equipped and maintained.

When the great people of these United States shall be educated as to their own duties, and it shall be made plain to them that their very lives depend on the observance of proper rules for their guidance and protection, there will be no necessity for such coercive and drastic penalties as have been contemplated.

The bureau of health should have control of all interstate and national questions of health matters, and should be co-operative and always be ready to render assistance in information or material.

This convention, should it earnestly, with no uncertain candor, give its support to such an organization as a national department of health, will not have been without avail in the eternal progress of our advancing civilization made possible under the benign and never-to-be-dimmed Star of Bethlehem.

Dr. Saunders deprecated the idea of centralization of power as being contrary to the spirit of the institutions of this country. He advocated a broad system of public health, rooted in the people from whom its support should be drawn.

At the close of Dr. Saunders' address the report of the committee on resolutions was called for and presented by Chairman G. D. Shands, who prefaced the report by stating that it had been unanimously adopted by the committee, after mature reflection and deliberation. The written report was read as follows:

The committee on resolutions, after careful consideration of the many valuable resolutions offered by the various members of the convention, have decided upon the following as embodying the ideas expressed in the majority of the said resolutions:

Therefore, That for the purpose of protecting and improving the general health of the people of the United States, co-ordinating and harmonizing the action of the State and National sanitary authorities; framing regulations for the treatment of infected vessels and material at all infected or suspected foreign ports of shipment; preventing unnecessary interference with commerce, the United States mail, or through traffic by land or water, and for adopting a uniform system of quarantine for all ports in this country; be it

Resolved, That there be established on a broad and comprehensive basis a National Bureau of Public Health in the Department of the Treasury of the United States, that the administration of all the public health functions now exercised by authority of the United States be placed in the hands of this Bureau.

2. That the sanitary authorities and commercial interests of the several States of the Union be brought into immediate relations with the Bureau and be given a due share in the power and responsibilities of the central board through the agency of an advisory council consisting of one member from each State, to be appointed by the authorities of the several States.

After the reading of the report its adoption was before the house for debate. Dr. Maury, of the Tennessee delegation, took the floor. As there was objection to the immediate passage of the resolution, an adjournment was taken until 3 P.M.

An executive committee was appointed, as follows, and they were instructed to use every effort to secure the passage of a law in accordance with the resolutions. The committee will themselves agree on a bill which meets the views of the Convention as thus expressed: Gen. Luke E. Wright of Tennessee, Dr. Ruhart of Maryland, Fred Orgill of Memphis, Dr. U. O. B. Wingate of Wisconsin, Dr. W. B. Horlbeck of South Carolina, W. H. Dwyer of New Orleans, J. T. Harahan of Illinois, and Dr. Samuel Durgin of Massachusetts.

At the opening of the afternoon session many amendments were offered, but were promptly voted down, and the original resolution was passed by an overwhelming majority. After the passage of the resolution and vote of thanks to the local committee, the convention adjourned.

The Plague in Russian Turkestan.—The public has been much alarmed at the few cases of plague in Vienna, but all danger seems to be over from this source. There is more to be feared, perhaps, from an epidemic of a disease supposed to be the plague, reported by the governor of Samarkand at the village of Kishlak, Ansord. The strictest measures were taken at once to prevent the spread of the disease; the chief of the Plague Bureau, Prince Alexander von Oldenburg, hastened to the spot; the village was disinfected, clothes burnt, etc., and a cordon of inhabitants of neighboring towns drawn around the place.

A New Institute of Hygiene.—The South Australian Institute of Hygiene and Bacteriology has been brought into active operation within the last two months. Its objects, among others, are to afford facilities for the study of bacteriology and hygiene, the encouragement of original research, the giving of lectures on sanitary subjects to sanitary inspectors, nurses and others. A very moderate scale of fees for bacteriologic examinations has been adopted. Dr. Borthwick, medical officer of health, Kensington and Norwood, has, we under-

stand, been very largely instrumental in founding the Institute, of which he is the honorary general secretary. We trust that the Institute will enjoy a successful and useful career.

Sanitary Operations at Santiago.—Gen. Wood is indefatigable, in sun and rain alike. The result of his labors is apparent in every branch of the service—civil and military. The patients are reaping the result in better attendance and improved food and cooking. People who have lived here a lifetime are unable to understand the extraordinarily low death-rate, averaging for October, up to date, ten a day. During the same period of last year the deaths averaged 183 a day. The 300 prisoners in Santiago prison will in future be made to work on building roads for the city. The rock will be hauled over the railroad from the Songo quarries. It will be delivered at the rate of forty cents a ton, and the railroad officials have offered to deliver 500 tons of rock free as their share of the work of improving the city.—*New York World*.

Typhoid Fever the Scourge of the Armies.—The lessons of some of our recent wars ought to be instructive to those who have the responsibility of placing a number of armed citizens in the field. Hitherto the lessons of war have been disregarded, though the teachings have been most emphatic. Disease kills more than the sword. This appears to be the inevitable course of wars. It was written in large letters in the Franco-Prussian War, and more fearfully still in the Crimean War. Since then in the Spanish-American War the ravages of yellow fever have been appalling, and now we learn that a telegram from Alexandria states that the men who have returned from the Nile continue to die like flies, from enteric fever, contracted possibly through the use of tinned beef, and certainly aggravated by immoderate indulgence in cheap, nasty spirits at fifteen-pence a bottle, the men having accumulated money in their pockets. The return states that every bed in the great hospital at Raseltin is occupied, besides which dozens of deaths occur weekly, and it is believed that ten per hundred of the British troops on the Nile are already affected. The disease is, moreover, following the troops into Crete. When tinned beef is fresh it is all right, but big tins rapidly spoil before the contents are consumed. The mortality during the whole campaign is probably less than the subsequent deaths from enteric fever.—*The Scalpel*, October.

Defective Hospital Arrangements in the Sudan.—The approaching home-coming of many hundred sick soldiers from the Sudan has revealed grave defects in the military hospital organization here. The fact is that at the present moment all these hospitals are already overcrowded, and the only way in which room can be made for the poor fellows now returning from the East is by driving out an equal number of men long before they are honestly cured. A few more weeks, or even days, of treatment would have saved such sufferers as future defenders of their country; but, as a matter of fact, the authorities, who expel still ailing men for want of room, satisfy their own consciences by labeling them invalids, and clearing them out of the service altogether. It is difficult to overestimate the number of soldiers England loses each year by this almost inhuman economy; and if the critics who have been lifting up their hands in holy horror at the shortcomings of our war surgery will now but look at home, they will find conditions—absolutely inadequate in a time of comparative peace—which would constitute the gravest scandal in a time of war. But the modern average Britisher, even the jingo, says in his heart, "There will be no war," and keeps his very hospitals on a scanty peace footing.—*The Outlook*.

The Seasons at Manila.—The seasons at Manila are described by the Spaniards as six months of mud, six months of dust and six months of everything. There is much confusion in the public mind just now as to the question of the health of

North American troops during a temporary sojourn in the Philippines, and also as to the larger question of possible acclimatization of our people in those islands, in case of permanent occupation. No definite answers can be given to these two questions, but in their consideration three things may well be borne in mind: 1. By means of strict observance of hygienic principles, the death-rate among foreigners in a tropic country can be very much reduced. This has been nowhere shown except in the case of the British troops in India and of the French troops in Cochin-China. 2. The great majority of the best authorities are agreed that complete acclimatization of Europeans—and hence, we may add, of North Americans—in the tropics is impossible. By exercising the greatest care, they may live in tropic countries, but, as has been well said by a recent writer, to tolerate a climate is one thing; to be independent of it is quite another. 3. The Anglo Saxons are universally acknowledged to be the least fitted, the Mediterranean nations the best fitted, to colonize in the tropics.—*Science*.

Pulmonary Tuberculosis.—Otis (*Am. Jour. of the Med. Sci.*, November) believes it problematic whether we shall ever be able to cure any large number of these cases by antitubercle serum, "for when the disease is once thoroughly established the infection becomes a mixed one, and various other micro-organisms are brought into play, and the whole system becomes involved." He considers prevention the most hopeful outlook—prevention by eliminating the bacillus and by establishing immunity to it through a normal standard of health. Properly conducted, compulsory registration of the sufferers need not work great hardship to the consumptives or their friends, but would be less necessary if physicians could be depended on to see that proper precautions were taken as to the disposal of the sputum and disinfection. Where preventive and disinfectant measures are difficult or impossible of execution, among the consumptive poor, especial hospitals should be provided. He gives the following instructions concerning the disinfection of a room that has been occupied by a consumptive: "Carpets, curtains and bedcoverings should be exposed to superheated steam under high pressure, or where facilities for this do not exist, they, with all stuffed furniture, should be thoroughly shaken and brushed, and exposed to the open air and sunlight for several hours. The floor and walls of the room should be rubbed with new bread, followed by the application of a 1 per cent. solution of chlorid of lime, or a corrosive sublimate solution (1 to 500); ceilings should be thoroughly dusted and white washed. Every corner wherever dust is likely to lodge should be carefully cleaned. The windows should be left open for twenty-four hours." Further, in dispensaries, etc., circulars with plain directions as to the avoidance of tuberculosis should be given each patient, and to the tuberculous ones, in addition, rules for disposing of the sputum.

Local Infiltration in Infections.—E. Centanni of Bologna announces, as the result of extensive study of the serotherapy of pneumonia (rabbits), that Behring's methods are ineffectual in this disease; the products are rarely active, and too uncertain to be depended upon when the disease is actively developing. But he found that he was able to extract from the cultures outside the body, harmless, rapid and concentrated vaccines which produced favorable results even when the disease was actively developing. He also found that this effect was due to the participation of the organism which they induced, and finally established the important fact that the organism possesses an extremely powerful immunizer in the local infiltration, which acts at the same time on the germs and on the products of their action on the tissues. Reabsorption of this infiltration or inoculation with the small amount of .5 to .2 centigram, confers upon the rabbit at one stroke, without any other preparation, a serum that arrests the pneumonic infec-

tion even at the moment of its highest activity, with a natural crisis. The action of the antipneumonia serum combined with the local infiltration proved so satisfactory that he extended his research to diphtheria. He found that while the infiltrate is powerless in this disease to prevent the action of the toxins upon the tissues, yet it succeeds in paralyzing the secondary products, and thus exerts its curative power at a period of the disease when the specific serum has ceased to be effective. He divides the infection into two stages: 1, the alterations produced in the tissues by the direct action of the germs or their toxins; 2, the products that are developed secondarily in the altered tissues. Immunity therefore must depend upon two factors: one to arrest the development of the primary germs and render their toxins harmless to the tissues, and another to promote the limitation and harmless reabsorption of the altered tissues at the local focus. The first immunizing factor is to be derived from cultures, either directly or by transformation, but the second factor is evolved by the elements of the body at the point of local reaction, and the moment to obtain it for use on others is when the infiltration is being absorbed into the circulation. The *Gazzeta d. Osp.*, xix, No. 103, contains the detailed report of his investigations.

A Decline in Birth-Rate.—At the Birmingham Congress of the British Sanitary Institute in September, Dr. Dawson Williams read a paper on the subject of "Decline in the Birth-rate of England and Wales," and said that when the census was taken in 1891 it was discovered that we had been making an overestimation of our population in England and Wales, and that, whereas the estimate expected an increase since 1881 of, in round numbers, three and three-quarter millions, yet the actual increase, as ascertained by enumeration, was only just over three millions. The growth of the population was determined by two factors—the balance between births and deaths, and the balance between immigration and emigration. The decline in our rate of growth has been due to a disturbance of both these balances. The births were 290,000 below expectation; emigration was 412,000 above expectations. The death-rate was lower, so that in fact, the natural increase on the balance of births and deaths ought to have been larger. He commented upon the diminished birth-rate, and ascribed it to a progressive decrease in the number of children born to married English and Welsh women, and thought this might be due to the fact that the average age at which women married was now somewhat later than formerly. It was a rather curious fact that the proportion of bachelors in a given number of males decreased steadily, not only during early adult life and maturity, but afterward also. The registrar-general concluded that "married life must in itself be more favorable to longevity than the condition of celibacy." Death or marriage appeared to be the alternative. The last census showed that both the urban and the rural population had increased, though not in the ratio expected; but the increase had been much less in the latter than in the former. In certain counties in which agriculture was the main industry, the rural population had actually declined. There were more infants born in towns than in the country in proportion to the population, but the infant mortality in towns was so much higher than in the country that the town excess of births failed to maintain an excess in proportion to the total population. The great improvements brought about by public health legislation had affected persons in adolescence and in early maturity. The decrease in the birth-rate would appear to be progressive, and by far the greater proportion of deaths in infancy were preventable.—*The Scalpel*, October.

Sanitation of an Oriental City.—The *New York Times* describes the radical measures adopted by the Japanese in Formosa, for the reclamation of a filth saturated city. Japan has, in the Island of Formosa, a possession that duplicates, on a small

scale, many of the administrative, economic and political problems which Cuba presents to her would-be regenerators, American and native. In Formosa, as in Cuba, the centers of population have for centuries been breeding-places of pestilence, aggregations of people rather than cities, and unprovided with even the rudiments of a sanitary system. On assuming control of the island, the Japanese first turned their attention, naturally, to the remedying of conditions from which their own soldiers and officials were sure to suffer severely. This task, everywhere difficult, they seem to have found impossible of accomplishment in at least one instance, for they have just decided that it will be cheaper and easier to remove the inhabitants of Teukcham, an important seat of trade, to a new site than it would be to make the present one even moderately healthful. So they have ordered 40,000 people to prepare for immediate removal from the infected and swampy ground on which the town now stands, and to take up their residence on a hillside several miles away. Here streets have been laid out like, but better than, the old town, and to every property owner there has been assigned a plot of land corresponding in position and size with that which he formerly occupied. Sewers, railroads, sidewalks, public buildings, water-works and many other improvements have been provided at Government expense, and, with further assistance, which the people will receive, it is expected that within twelve months the transfer will have been effected with an amount of individual loss and hardship not worth considering in comparison with the benefits secured. A Formosan town is a very different thing from a Cuban city like Havana or Santiago, and what is practicable enough in the one case could hardly be attempted in the other, but there is none the less a valuable suggestion in this Japanese "short cut" to health and safety. Cuba has many good harbors, occupied now by only small and easily handled villages. By judicious selection among these it would not be impossible gradually to attract population, especially newcomers, and so start even with the microbes and bacteria.

SOCIETY NEWS.

Cincinnati Academy.—At the regular meeting of the Academy of Medicine, November 14, Dr. C. D. Palmer read a paper entitled "What is the Proper Field of Salpingo-oophorectomy?"

Society for Original Research.—At the regular meeting, held in Cincinnati, November 10, the program was: Two brain tumors, by Dr. F. W. Langdon; histologic specimens, by Drs. Freiberg and Rowe; "The Anatomic Basis of Neuralgia of the Temporal Bone," by Dr. Robert Sattler.

American Humane Society.—At a meeting of the Joint Committee on Vivisection of scientific societies of Washington, D. C., November 12, the following resolution was passed:

Resolved, That the Secretary be authorized to call the attention of the prominent medical and scientific journals of the country to the importance of the meeting of the American Humane Society to be held in this city in December proximo, and to request that editorial notice be taken of the danger that the influence likely to be exerted at that meeting may cause the Vivisection Bill now pending in the Senate to be called up and passed.

It is also requested that our readers write to their respective senators and representatives in regard to the matter.

Washington Medical Society.—At the meeting of the society held November 16, Dr. Shands presented skiagraphs illustrating the value of X-rays in the treatment of fractures of the long bones. He showed a number of cases of deformity from old fractures which he had subsequently cured by wiring. One skiagraph showed the entire pelvis and both legs. Dr. Carr reported a case of ruptured spleen. The case was that of a child 10 years of age, who had been kicked by a mule and brought to the Emergency Hospital for treatment. On the

second day he opened the abdomen, found a ruptured spleen, which he removed, the child making an uneventful recovery. Dr. Galzebrook presented a dentigerous cyst which he removed at an autopsy; the growth was about the size of a small apple and contained two well-formed teeth; he presented two kidneys, each of which showed an anomalous arterial supply, each having three renal arteries. The ureter entered the pelvis of the kidney by three or four openings in each specimen. He also presented a tubercular abscess of the lung with the abscess covered with hard, chalky deposit. The pleura was also studded with chalky deposits.

Washington Medical Association.—An adjourned meeting of the Medical Association of the District of Columbia was held November 15, to receive the report from the Standing Committee on Hospital Dispensary Regulation. The committee reported that the staffs of the following institutions had presented satisfactory proofs that they were enforcing the recent regulation of the association regulating the admission of free patients: Central Dispensary and Emergency Hospital, Dorothea Dix Dispensary, Eastern Dispensary, Woman's Dispensary, Children's Hospital, Columbian Hospital, Garfield Memorial Hospital, Lutheran Eye, Ear and Throat Dispensary, South Washington Dispensary, Columbian and Georgetown University Hospitals. The committee said: "We find that the Dorothea Dix Dispensary has on its attending staff others than members of the association, but those who are members expressed their determination to comply with the regulations." In the opinion of the committee the system in vogue to a certain extent, in the Providence Hospital, by which the resident physician, who is not a member of the Association, but renders service to private patients in pay-rooms, is reprehensible, and calculated to deprive members of the attending staff and the profession at large of proper remuneration for their services. The committee was instructed to report the names of physicians connected with hospitals of the District who are not members of the association, and to recommend a plan for correcting the abuse cited in their report.

NECROLOGY.

PHILANDER VIRGIL BENSON, M.D., Baltimore, Md., November 10, aged 60 years.—**Herman A. Borger**, M.D., Chicago, November 18, aged 38 years.—**C. J. Heckert**, M.D., Harrisburg, Pa., November 13, aged 50 years.—**H. S. Howell**, M.D., Kansas City, Mo., November 13, aged 40 years.—**James M. Smith**, M.D., Cheswold, Del., November 12, aged 62 years.

JAMES D. MONCURE, M.D., superintendent of the Eastern State Hospital, died at Williamsburg, Va., November 9. The Doctor was born in 1842 and began his study of medicine in Heidelberg University, Germany, after being a student at Bernhardt, Austraelli, Meindirgen, Germany, and in College Rollin, Paris. After the Civil War he was graduated from the University of Maryland and, in 1884, was elected superintendent of the above asylum.

JOSEPH UNDERWOOD HALL, M.D., Jefferson, 1859, died at his home in San Jose, Cal., November 14, aged 85 years. He was a native of Kentucky, and during the Civil War had charge of the Union Hospital in Glasgow, Ky.

B. ABBOTT LINDSAY, M.D., College of Physicians and Surgeons, New York, 1881, died at his residence in New York City, November 13. He was born in Lancaster, N. H., forty-two years ago.

CHARLES C. EDWARDS, M.D., Jefferson, 1875, born in Gibson, Pa., seventy-three years ago, died at his home in Binghams, N. Y., November 16.

EMIL SCHOPEN, M.D., University of Berne, Switzerland, 1884, of Yonkers, N. Y., fell dead in his office November 17. He was well known for his feats in plastic surgery.

BARBOUR.—Dr. Philip Stanhope Barbour, for the past eight years the efficient superintendent of the Louisville City Hospital, died there on the 14th inst., after a lingering illness. He was born in Jefferson County, in September, 1847, of an old and honored family. At that time his parents resided eight miles from Louisville. He attended such schools as were in the neighborhood for several years, and later took a course at a college at Bedford, Ind. In 1867 he went to Philadelphia, where he attended the Jefferson Medical College. After receiving his diploma from this college he returned to Louisville and began the practice of his profession. He soon attained prominence and acquired a splendid practice. About twelve years ago his hard work began to tell on him and his physicians advised him to seek a colder and more settled climate. He then sought and secured a position under the United States Government as physician to the Indians at the Cheyenne Agency in Northern Dakota. After a brief stay at home in Louisville he found he would have to leave again, and secured the appointment as physician to the Kaw Indians in the Indian Territory, where he remained sixteen months. In 1890 Dr. Barbour returned to Louisville and soon after was appointed superintendent of the City Hospital, which place he has held ever since. Dr. Barbour married Miss Rebecca Tarlton in 1869; she and two children survive him: Mr. Philip D. Barbour and Mrs. Dr. Ellis Duncan. The Doctor made a great record as superintendent at the City Hospital. Many changes have taken place in the hospital during his incumbency, as when he first assumed charge the place was a disgrace to the city, the buildings reeking with vermin, without repair since they were used during the war as a military hospital. Suggestions from Dr. Barbour were largely the cause of the improvements which have taken place. He saw the building enlarged, thoroughly renovated, a new laundry building added, fire escapes erected, a change of system in the training-school for nurses, the installation of the ambulance service, the erection of a pathologic department and postmortem room and amphitheater, and the beautifying of the grounds. He has been able to work amicably with a number of changes in the mayoralty, under a board of charity commissioners and later under a board of safety. During the eight years that he had been connected with the hospital he took but three weeks' vacation, he was up early and late, and no one had more warm personal friends.

PRACTICAL NOTES.

(Continued from page 1306).

Chronic Suppurations of the Middle Ear.—E. Schmiegelow describes 96 cases he has operated and gives tabulated details, in the *Nordiskt Med. Arkiv*, 1898, No. 17. He has operated over 300 in all. In 23 cases the affection had lasted eleven to twenty years; in 17, from one to five years, and in one case between forty and fifty years. The mastoid apophysis was alone opened in 20 cases, with 55 per cent. cured; in the rest, the otitis was not arrested. The attic was opened in 14 cases; 7 were cured, 3 improved; 1 relapsed and in 2 the result is unknown. In 53 cases the entire middle ear was opened and 70 per cent. cured. In 7 cases the operation was not completed. In 9 cases there was improvement; 3 cases died—miliary tuberculosis, or meningitis. The transverse sinus was opened once. In 4 cases the operation was followed by traumatic facial paralysis. He states that the patient must be prepared for the tediousness of the after-treatment. In one of his cases it required a year and a half; in several six to nine months, but the average limit was two to four. In 58 cases nothing could be learned as to the etiology. In 10 it commenced as an acute suppuration after influenza. In 3 it was evidently a carious process due to the presence of adenoid vegetations. In 4 cases the suppuration was tuberculous. In 2

it was the result of whooping-cough, in 11 of scarlet fever, in 2 of measles, in 5 of trauma and in 1 case there was a carcinomatous growth. The hearing was unaltered after the complete operation in 8; more or less improved in 27.

Meta-Cresol-Anytol in Erysipelas.—Anytin, the new substance that renders insoluble substances soluble, was described in the *JOURNAL*, xxx, p. 887, and the promising results attained with it in combinations, especially meta-cresol-anytol, in diphtheritic and other bacterial processes. The *Deutsche Med. Woch.* of October 27 contains the report of extensive tests at Loeffler's Hyg. Institute, which show that painting the erysipelatous patch with it will check its development and arrest the infection. The results are so encouraging that further tests are now being made in other bacterial and parasitic affections.

Albuminuria in Malarial Fever.—Thayer presents an analysis of 758 cases of malarial fever occurring in the Johns Hopkins Hospital during eight years, in the *Am. Jour. of the Med. Sci.* for November. Albumin was present in 321 instances, i. e., 46.44 per cent., in the majority of the cases there being but a small trace of albumin. In 121 cases, or 17.5 per cent., casts of the urinary tubules were found. In the regularly intermittent fevers, tertian and quartan, the proportion of cases of albuminuria was 38.6 per cent., while in the estivo-autumnal infections, the majority of all cases—58.3 per cent.—showed albumin in the urine."

Bactericidal Properties of the Becquerel Rays.—Becquerel established that phosphorescent bodies, especially the salts of uranium, absorb the most refrangible and the ultra-violet rays, and emit rays that will pass through certain substances opaque to the sunlight. They will even pass through several substances opaque to the Roentgen ray and can be refracted and polarized. Pacinotti and Porcelli have been studying their bactericidal properties, using for the purpose freshly pulverized metallic uranium, exposed to the sunlight, and then kept at a temperature of 44 to 55 degrees C., without contact with the air. Various germs exposed to the action of the rays thus generated were all killed in the space of three to twenty-four hours, and the microscope showed alterations in their shape, indicating some chemic effect on the protoplasm (staphyl.; strept.; pyocyanus; proteus; germs of cholera, tuberculosis, diphtheria and typhus.). They also injected 5 cm. of a very virulent bouillon culture of the streptococcus under the skin of the ears of a rabbit, and exposed one ear to the action of the Becquerel rays, which prevented the evolution of any inflammation, while the non-exposed ear ran the usual course of a streptococcus invasion. The *Gazette degli Osp.* of September 25 observes that the "experience and skill of the investigators, the precision of their work and the innumerable control tests, render this announcement extremely interesting and encouraging."

Typic Osteomalacia in Children.—F. Siegert reports a personal case and adds three from literature, in which all the bones were macro- and microscopically affected with typic osteomalacia. Three were girls of 13, and the fourth a boy, dying at 18 years. All were of infantile habitus. The disease lasted three years in three cases, six in one. All had spontaneous fractures of the lower extremities, decrease in size, assisted by the curvature of the spine and limbs. In three cases there had been a slight, soon outgrown rachitis in early childhood. As phosphorus treatment is a direct specific for osteomalacia of the growing or developed skeleton, the importance of an early recognition of the affection is evident.—*Munich Med. Woch.*, November 1.

Nasal Discharge of Liquor Cerebrospinalis.—Körner has collected nine cases, one personal, in which there was a discharge of a clear aqueous fluid through the nose, about 15 c.c. an hour, with disturbances in walking and bilateral atrophy of the

optic nerve. The similarity of the cases inclines him to group them all as a special syndrome caused by a tumor of the glandula pituitaria breaking through into the sphenoidal sinus.—*Munich Med. Woch.*, October 25.

Cicatrization of Wounds of the Liver.—Cornil and Carnot report experimentation with dogs, from which they apply the conclusions to man that in case of a simple, not very extensive wound, the hemorrhage can be arrested after opening up the organ with laparotomy, by pouring 10 per cent. gelatin on it. If the wound is more extensive, the lips are brought together with a ligature in Glisson's capsule. A little fibrin or blood-clot between the two surfaces of the wound will not interfere with the cicatrization, but will provide nutritive material for the cells of connective tissue and endothelial cells of the vessels, which are to form the cicatrix and serve as a support for them. More or less extensive pieces of the liver substance can be removed to make the wound more even. If the loss of substance is superficial, a layer of the great omentum can be sutured with a stitch or two to Glisson's capsule. When there is much loss of substance it can be replaced by human fibrin or a piece of sterilized sponge, impregnated with the yolk of an egg, or not. The sponge offers more resistance and fills the cavity better, but the organization of fibrous tissues is less rapid with it. Their article in the *Semaine Méd.* of November 2, is profusely illustrated.

Actinomyces of the Umbilicus.—A farm-hand working naked to the waist became infected through the navel. The actinomyces yielded to potassium iodid, but the case suggests the danger of working naked while harvesting, and the necessity of extra cleanliness (*Bull. de l'Acad. de Méd.*, October 18). A farmer with actinomyces of the neck was also recently observed by Lucas. Besides the actinomycetes in the pus they were also found in the apparently normal portions of the omohyoideus muscle.—*Munich Med. Woch.*, November 1.

Schweninger's Cure for Obesity.—Prof. H. Cohn, the Breslau ophthalmologist, recently visited the Schweninger establishment and witnessed such remarkable cures that he describes his experiences at length. One woman has lost fifty pounds in eight weeks; another twenty in five weeks, and another who weighed 240 pounds when she arrived had reduced her weight to 145 when she left. From exhaustion at the slightest effort, the patients could take long walks and climb hills without fatigue, with the heart working normally. The treatment is threefold: massage, hot baths and diet. The massage is done by the physician, for fifteen minutes, before meals. The patient is instructed to breathe deep, which is considered one of the most important factors of the results attained with the massage. The abdomen is kneaded and finally large pieces of the derma are taken up and squeezed energetically between the hands to crush the subcutaneous adipose lobules. In conclusion the masseur gets on the patient on his knees and digs them into the epigastrium while the patient takes several deep breathes. Cohn describes his consternation at this sight, but the patients did not seem to mind it much, although they frequently drop to sleep afterward from exhaustion, and the abdomen is covered with ecchymoses. The twenty-minute hot baths are given to the arms, feet or a sitz bath, on separate days, never the entire body at once. The water flows in and out of the tub at a temperature increasing from 30 to 40 degrees R. The food is served in tiny doll dishes and only a pint of liquid is allowed during the entire day (Gerolstein sprudel water). Bread, cake, butter, fat, sugar, coffee, tea, milk, wine, beer and brandy are rigorously excluded from the diet, but eggs, ham, roast meats, fruits, vegetables, etc., all in small amounts, afford a varied menu for the four meals. The patients gradually become accustomed to the dry diet. Constipation is controlled by aloes pills at night or an injection of five grams of glycerin in the morning. The Sunday is a day

of rest for all, and the rules are suspended. Six to eight weeks are required for the cure, and the patient, to retain the benefits, must not return at once to his former habits of life.—*Presse Méd.*, October 28.

Mud Baths.—Thiroux summarized the general action of mud baths at the International Congress of Hydrology, etc., at Liège, as accelerating the number, while diminishing the amplitude, of the respiratory movements, increasing the arterial tension and the pulsation, stimulating the central nervous system and the peripheral nerve terminals, increasing muscular excitability, compressing the articular surfaces, stimulating nutrition of the bones, increasing the electrocutaneous sensibility and the central and peripheral temperature, exaggerating the perspiration and increasing oxidation processes and the elimination of organic waste. The local action is emollient, owing to the vegetable substances they contain. They progressively relieve congestion and stimulate the circulation in the skin and muscles, while they have a special thermic action owing to the extreme heat possible to be endured without inconvenience by the subject, and for long periods. They buoy up the body with a peculiarly sedative effect, and stimulate the general nutrition and nerve terminals, with a subsinapism of the skin, indicated by the "mud false eczema." He described the fine results attained at Saint Amand in the cure of phlebitis, and chronic troubles induced by a defective venous circulation in the lower members, also in gynecologic cases, concluding with the statement: "Mud baths are therefore the thermal medication par excellence on account of the general stimulation of the organism and the local effects. They stand at the head of modifying and altering measures. Chronic torpid affections, gout, chronic rheumatism, hydrarthrosis and various forms of arthritis, ataxia, etc., are especially amenable to their action."

Prolapsus of Urethra in the Female.—B. Singer has had occasion to observe eight cases at Chrobak's clinic, generally children or women in the menopause. It is caused by an angioma, by relaxation of the tissues or the introduction of foreign bodies. The symptoms are pain in urinating, tenesmus, occasionally inflammation and hemorrhage; sometimes there are no appreciable symptoms. Treatment can only be surgical in a pronounced case.—*Monatssch. f. Geb. u. Gyn.*, October.

Recurrence of Measles.—Vergely reports a case of recurrence two weeks after the initial attack, the first in thirty-one years' experience. The average interval of the cases on record was from the sixth to the sixtieth day.—*Munich Med. Woch.*, November 1.

Alcohologenic Cardiac Epilepsy.—A. Smith applies this term to an epileptoid condition accompanied or preceded by dilatation of the heart. As the state of the heart improves, the epilepsy disappears also. The dilatation of the heart is purely alcohologenic and subsides completely with abstinence from alcohol in some cases, or partially in others, with slight recurrences for a while. In the first group, a slight excess of alcohol above very moderate amounts will induce the attack. In the second group the intolerance to alcohol is not so pronounced. Complete abstinence is the only cure, combined with medication to strengthen the musculature of the heart.—*Munich Med. Woch.*, October 25.

After Care of the Insane.—Germany was really the originator of the excellent plan of taking oversight of the recovered insane, as of so many others by which mankind have benefited. Its first practical promoter was the Hofrath Lindpaintner of the Duchy of Nassau (born 1793, died 1848), whom Dr. Damerow of the Nettleben Asylum described at his death as "perhaps the last non-medical director of a German institution for the insane," and who himself published in 1844, at Wiesbaden, his useful "Nachrichten ueber die herzogliche Nassauische Irrenheilanstalt zu Eberbach, im Rheingau, von ihrer Begrü-

endung (1815) an bis zum Schlusse des Jahres 1842." Midway of this period, Herr Lindpaintner founded the first patronage society. Dr. Earle, who visited Eberbach in 1849, just before its patients were removed to their present asylum on the Eichberg, said in his "German Asylums," published in 1852-53: "In 1829 a Society of Patronage was originated by Mr. Lindpaintner, who became distinguished for the energy and ability with which, as director, he managed the asylum. This society was probably the first of the kind. To the poor who are cured it extends its care and assistance during a period of two years after they leave Eberbach. Up to the year 1844 it had assisted 81 persons, at an expense of 1349 florins." It was then in quiet but successful operation a dozen years or more before a similar move was made at Paris. It seems to me that this statement is due to the memory of one of the early reformers of insane care, in a country of which we hear much less on this subject than of France and England, especially in the period preceding Dr. Earle's very useful book. But I may also call attention to a matter which Dr. Stedman and his colleagues overlook—that the boarding-out system for the insane of Scotland, Belgium and some parts of Germany, gives one of the best opportunities for "after-care," and is so used in those countries to some extent, as it was by me during the three years (1885-88) in which I introduced and managed the Scotch system in Massachusetts. Some very striking examples of virtual recovery and self-support occurred among the 180 patients whom I placed in families, in consequence of the after-care which the State then exercised in such cases; and I doubt not more have occurred in the ten years since I ceased officially to exercise such after-care.—F. B. Sanborn, in *Boston Med. and Surg. Journal*, March 24.

MISCELLANY.

The "Medical Record" Again.—Our attention has been called to an article in the *Medical Record*, entitled "Recent Experiences in Military Surgery after the Battle of Santiago." The *Record* says: "THE JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION of November 12 publishes an article with the above title, suppressing the name of the author, which article is lifted bodily from the *Medical Record* of July 30, 1898, its aspect, however, being altered by the insertion of illustrations. A clear case of kleptomania." The truth about the matter is that Professor Senn wrote his article in duplicate. One article, with the illustrations, was sent to this office, which, by the way, is in his own hand-writing. The other was sent to the *Medical Record*. In the fullness of time the JOURNAL published the article, which was as much its property as any other article which has come into the JOURNAL office. The *Record* having published it first, however, we would not have republished the article but for the imperfect manner in which it appeared in the *Record*, as without the illustrations this report was almost valueless. Still, however, we presume it was good enough for the *Record*. In regard to suppressing the name; this is a prevarication, as the name of Professor Senn appears in the contents and title pages of the JOURNAL in its proper position, and also first in the "Miscellany" of the same number, the error having been discovered after the article in question had been passed through the press. An error so seldom appears in the JOURNAL that it is naturally an object of mark by our esteemed contemporary.

Black Excretions in Hystero-Epilepsy.—The *Gazz. degli Osp.* of September 13 relates the case of a lad of 13 years, a hystero-epileptic, through whose skin exuded a black substance, while the urine was also blackish and the feces covered with a black layer. When the lad was sent up to Naples, the phenomenon seemed to be arrested, but returned again after his return home to Calabritto, when he also vomited the black substance.

Zuccarelli personally saw the black substance oozing from the skin. It looked like coffee grounds, and left inky tracks on the skin as it slid down. The substance contained some mineral elements, but he could not discover any hematoxin or any other organic substance. He is inclined to connect it with the antitoxic theory of epilepsy, but in a discussion at the Naples Accademia Med.-Chir., others attributed it to the hysteria. Gallozzi also described a case, a relative of a Neapolitan physician, a classic hysteric, in whom intestinal occlusion suddenly appeared, with stercoral vomiting and exudation of stercoral matter through the mammae and axillae. She recovered after two months of complete occlusion.

New York State Hospital for the Insane.—The recent propositions for the construction of colony buildings for 2260 patients at Central Islip, New York, is an exemplification of what can be done with limited means, and well done. The buildings are largely fireproofed; that is, the central buildings, all connecting corridors and two floors, beside fire-proof party-walls. The building specifications call for the best quality of construction, and provide for the completion of the group in every detail, ready for occupancy, including water-supply, heating, lighting, plumbing, and fire protection. The aggregate for the whole work is less than \$500 per patient. This furnishes a marked contrast with former palatial designs that have cost more than \$3,000 per capita, and which will not compare in efficiency to the Central Islip group.—*Charities Review*, November.

Effect of Altitude on the Blood.—The increased number of red corpuscles noted in high altitudes has been found to be due almost entirely to errors in the Thoma-Reiss apparatus, caused by the differences in the atmospheric pressure, as has been confirmed by Gottstein's tests with it in the pneumatic cabinet. Schröder and Meissen have corrected this defect by making a deep groove around the edge, into which the glass cover fits air-tight and excludes the outside air completely. The question is now ready to be investigated anew, eliminating this cause of error.—*Munich Med. Woch.*, Nos. 4 and 42.

Left-Handedness.—A. Rothchild attributes this condition to lack of proper training in childhood, and relates a case of a 4-year-old girl whom he cured permanently by hypnotic suggestion.—*Vienna klin. Rund.*, October 23.

Puberty.—A. Marro, who is with Lombroso, the founder of the new school of criminal anthropology, has been studying the subject of puberty in its relations to anthropology, psychiatry, pedagogics and sociology, and asserts that marriage between two healthy persons after they have both attained their full development—beard, muscular and skeletal development, habits of work and money-saving in the man; and bosom, adipose tissue and grace of outline in the woman, is the ideal from every point of view. Before this period sexual intercourse is directly injurious to the development of mind, body and character. It favors a return to savagery; the abnormal development of one function at the expense of the growing organism as a whole, the strife with rivals, the efforts to win the favor of the other sex, leading to thefts and other crimes, the degenerate offspring that are born to immature parents, etc. From every point of view therefore, the efforts of educators and social conventionalities should be exerted to delay the precocious gratification of the sexual instincts. But arrived at nubility, it is equally important that the sexual instinct be legitimately gratified, and this can not be accomplished by masturbation, promiscuous intercourse or free love. Besides the dangers of disease and excesses, they incite to sexual strife; activity is diverted from the wholesome field of social virtues, and the character warped, rendering it deceitful, combative and cruel. He is heartily in favor of forbidding marriage to degenerates, and denounces the marriage of an old man to a still menstruating woman, on account of the degener-

eracy of the offspring in both cases, affecting the second generation if not the first.—From abstract in the *Journal de Méd. de Paris*, October 30.

Congenital Syphilis.—R. Hecker has been studying the variations from normal in over a hundred children born dead or dying soon after birth, with congenital syphilis, and publishes his conclusions in the *Deutsches Arch. f. Klin. Med.*, 61, No. 1. He notes that the vessels of the umbilic cord are always affected with specific lesions, which can aid the diagnosis in living children. Typic osteochondritis of the long bones is frequent, but not invariably present. The spleen was found swollen in every case. The kidneys also are always diseased in congenital syphilis, evidenced by albuminuria in children that survive. The liver is invariably swollen and with syphilitic manifestations.—*Munich Med. Woch.*, October 25.

Exophthalmic Goiter.—A theory is proposed by C. Schwerdt of Gotha, in a long communication to the *Munich Med. Woch.*, concluding in No. 44, which explains exophthalmic goiter as a disease of the lymph and blood caused by nervous influences, in which the etiologic factors are an abnormal assimilation of chyle, an abnormal circulation of lymph and an abnormal activity on the part of the thyroid gland. There is also an abnormal circulation in the collateral routes, manifested by intermittent edema, which should rank with the triad: exophthalmus, tachycardia and struma. The variations depend upon the individual or inherited predisposition of the organism or its parts. In persons with strong muscles, instead of compensation in the line of atrophy of the hollow organs, it takes the form of hypertrophy of the muscular wall and there is enteroptosis. In others, with rudimentary enteroptosis, the atony of the lymphatic system leads to typic morbus Basedowii. Still others drift into myxedema or sclerodermia as they enter life, and theoretically must have passed through morbus Basedowii during their embryonal existence. These facts explain why neurasthenia, general atony and enteroptosis are becoming more frequent, while cases of exophthalmic goiter are rarer, and myxedema and sclerodermia still more seldom seen. An alteration of the nervous system, of the psyche is the fundamental cause, and in the strengthening of the psychic forces lies the road to recovery, so that the physician, whatever means he adopts, is after all a psychotherapeutist.

Askanazy states in the *Deutsches Arch. f. Klin. Med.*, 61, 2, that in four cases examined, he found in each one an extensive and well-defined affection of the striped muscles; the muscles grown through with fat, interstitial lipomatosis. The patients were emaciated. This hitherto unnoticed lesion explains the muscular weakness, the trembling, the insufficiency of the ocular muscles, etc. The nervous system was found intact to its finest ramifications in the muscles in each case. The thyroid had the usual characteristic alterations.—*Munich Med. Woch.*

Laryngitis Rheumatica Circumscripta.—Uchermann describes a form of primary acute laryngitis, occurring where there is a rheumatic predisposition, without catarrh, but with solid infiltrates which rapidly disappear under salicylic acid.—*Munich Med. Woch.*, October 25, from *Cbl. f. In. Med.*, No. 39.

Laparotomies at Home.—Professor Rydygier has become convinced that the dangers of infection are less in a private residence than a hospital; the germs encountered are not pathogenic or have not acquired virulence by "passages." He therefore advises patients with a well-lighted room and means sufficient to pay for the more expensive home after-treatment, to be operated on in their own residences. He does not consider it necessary to remove more than the curtains, portieres and carpets from the room.—*Vienna klin. Woch.*, November 3.

Cerebrotome and Aspirator.—Radojewski describes a new instrument for very small pelvis which is manipulated entirely outside of the genital parts, thus reducing the danger of infec-

tion and injury. After the trunk is born the spine is cut at the second or third dorsal vertebrae, and the brain chopped fine through the foramen spinosum and aspirated out, when the empty skull can be easily extracted.—*Deutsche Med. Woch.*, 1898, No. 42.

Sail-Cloth Operating-Table.—Professor Rydygier attributes the pneumonia that so frequently follows operations, to the chill from the glass or metal table top, and obviates this by having a sail-cloth top made to fit over the iron frame, and removed and washed after each operation. If a solid top is indispensable he uses one of hard wood. The last thing before operating, he washes his face, wets his beard and hair, rinses his mouth and gargles with some antiseptic fluid, which he confesses produces rather a sensation among the spectators. He never uses gloves, mask or cap, but has a couple of basins beside him to rinse his hands frequently during the operation, to mechanically remove any germs that alight after his preliminary painstaking disinfection. He rejects brushes and sponges on account of the difficulty in sterilizing.—*Vienna Klin. Woch.*, November 3.

Alvarenga Prize.—The College of Physicians of Philadelphia announces that the next award of the Alvarenga Prize, being the income for one year of the bequest of the late Senor Alvarenga, and amounting to about \$180, will be made on July 14, 1899, provided that an essay deemed by the Committee of Award to be worthy of the prize shall have been offered. Essays intended for competition may be upon any subject in medicine, but can not have been published, and must be received by the secretary of the college on or before May 1, 1899. Each essay must be sent without signature, but must be plainly marked with a motto and be accompanied by a sealed envelope having on its outside the motto of the paper and within the name and address of the author. It is a condition of competition that the successful essay or a copy of it shall remain in possession of the college; other essays will be returned upon application within three months after the award. The prize for 1898 has been awarded to Dr. S. A. Knopf of New York city, for his essay entitled: "Modern Prophylaxis of Pulmonary Tuberculosis and its Treatment in Special Institutions and at Home."

Calmette's Gift.—Dr. Calmette has presented to the Pasteur Institute at Lille, of which he is superintendent, 250,000 francs, which represent the profits realized in the distilleries at Seclin by one of his inventions.—*Progrès Méd.*, October 29.

International Memorial Honors.—The monument erected by international subscription at Copenhagen, to Meyer, the author of the first works on adenoid vegetations, was recently unveiled, with an address by Sir Felix Semon, the distinguished English laryngologist.

Co-operative Surgery and Medicine.—Legendre is trying to organize an association in Paris to be composed of both physicians and surgeons, meeting from time to time to study important questions together from their different points of view, each benefiting by the experience of the other.—*Progrès Méd.*, October 29.

Responsibility of the Surgeon.—A woman died recently from sepsis, at Lyons, France, after an operation by a prominent surgeon, and the husband sued for damages. The court decreed that it "would be excessive to hold the surgeon responsible for the unforeseen, extraordinary, sometimes even improbable complications, that may occur in any surgical intervention, even the most inoffensive. Such responsibilities would render the practice of medicine impossible in many cases." The plaintiff was condemned to pay the surgeon's fee of 200 francs and the costs of the suit, as the "death was merely a much-to-be-regretted misfortune, escaping all the previsions of science, as occurs at times, in spite of all the precautions suggested by human wisdom."

Not Responsible for Acts of Physician.—On the appeal of the Louisville & Nashville Railroad Company vs. Foard, a personal injury case brought by Foard against the company, the company insisted that the trial court had erred in permitting the plaintiff below to prove by himself that the attending physician and surgeon, who was furnished by the Company to treat his injuries, sustained in its service, was negligent in his treatment of the wounds, and that he was rough in his treatment of him, witness going into detail, and that by reason of this bad treatment his leg had to be amputated the third time. With this contention of the Company the court of appeals of Kentucky agrees, holding, Oct. 7, 1898, that the admission of this testimony was improper. It says that the Railroad Company was in no way responsible for the acts of the physician, or for his neglect of the plaintiff, unless it were shown that the Company was careless and negligent in his selection and that he was incompetent. It maintains that in the employment by a railroad company of its surgeons to attend the persons injured by its trains, the relation of master and servant and principal and agent does not exist; and that if the railroad company is careful, and selects suitable surgeons, it is not responsible for their neglect or malpractice. In this case there was no pretense that the Company was careless or negligent in the selection of this physician and surgeon, or that he was in any way incompetent, and, consequently, for the reasons stated, the court insists that the plaintiff should not have been permitted to prove the misconduct, neglect, or maltreatment of the physician, in this action against the Railroad Company.

Need Not Submit Blindly.—A man 56 years old stumbled over a large flat stone which was near the middle of, and several inches higher than, the sidewalk. There was evidence tending to show that he fell violently and sustained, among other injuries, a rupture. But when he sued the city for damages, it set up, as one of its defenses, that the next morning after the accident the plaintiff was advised by the hospital surgeon to have an operation for hernia performed, and that he obstinately and unreasonably refused to do so. The plaintiff admitted that he was advised to undergo the operation, and made a mistake in not accepting the advice. When it came to charging the jury, the trial judge said that the plaintiff was bound to use ordinary care to cure and restore himself, and to use such methods reasonably within his reach as would make his damage as small as possible; that he could not recklessly enhance his injury, and charge it to the defendant; and that, if the jury believed that the plaintiff declined to act upon the advice of the house-surgeon and declined to submit to an operation for the radical cure of his hernia, the defendant was not chargeable with the consequence of his refusal. But the second appellate division of the supreme court of New York says, *Williams vs. City of Brooklyn*, Oct. 18, 1898 (53 New York Supplement 1007), that this was a statement of the law more favorable to the defendant than was needed. It holds that the plaintiff was not required to submit blindly to professional advice. He was entitled and bound, it insists, to exercise reasonable judgment, and if his conduct was that of a reasonably prudent man he was within his rights in refusing to submit to an operation, and could not be charged with negligence in that respect. It may be added that on this question the jury found in the plaintiff's favor, and the appellate division affirms a judgment in his behalf.

Admission of Expert Witness.—Two things, the supreme court of Pennsylvania says, must concur to justify the admission of an expert witness: 1. The subject under examination must be one that requires that the court and jury have the aid of knowledge or experience such as men not specially skilled do not have, and such, therefore, as can not be obtained from ordinary witnesses; 2. The witness called as an expert must possess the knowledge, skill or experience needed to inform and

guide the court and jury in the particular case. Upon such a question such a witness may be called, and may testify not merely to facts, but to his conclusions from the facts, because the court and jury are without the knowledge necessary to enable them to draw the conclusions for themselves without aid. Thus, the court holds, Oct. 17, 1898, in the homicide case of *Commonwealth vs. Farrell*, that the question about the length of time after death when rigor mortis may be expected to set in was a question for expert medical testimony, though long experience and observation might stand in lieu of the study of books, and qualify one to speak as an expert upon this subject. But the witness called in this case as an expert upon this question had no medical knowledge, had read nothing on the subject, and had no experience except as an undertaker's assistant in preparing dead bodies for burial, and his attention as an undertaker did not seem to have been specially directed to this question, while he frankly stated that he was not an expert upon the particular subject. For the reasons stated, the court holds that he was not competent to testify as an expert upon that question.

Marriage no Defense.—In a prosecution for ravishing a female who was under 18 years, the fact that she has forgiven the accused, or has subsequently entered into the marriage relation with him, the supreme court of Kansas holds, *State vs. Newcomer*, Oct. 8, 1898, will not constitute a defense, nor relieve him from the consequences of the crime. The explanation vouchsafed by the court is that, the female being under the age of consent, her consent to the sexual act constitutes no defense, and neither her forgiveness nor anything which either or both may do will take away the criminal quality of the act, or relieve the defendant from the consequences of the same. The principle of condonation, which obtains in divorce cases, where civil rights are involved, has no application in prosecutions brought at the instance of the State for the protection of the public, and to punish a violation of the law. It is true, continues the court, that society approves the act of the defendant when he endeavors to make amends for the wrong done to the injured female by marrying her; and usually a good-faith marriage between the parties to the wrong prevents or terminates a prosecution, but the statute which defines the offense, and declares punishment therefor, makes no such provision. Finally, the court says, if the defendant has acted in good faith in marrying the injured one, and honestly desires to perform the marital obligations resting upon him, and is prevented from doing so by the influence and interference of persons other than his wife, it may constitute a strong appeal to the prosecution to discontinue the same, or to the governor for the exercise of executive clemency; but, as the law stands, it furnishes no defense to the charge brought against the defendant.

Indiana Dentistry Law.—Section 5596 of the Revised Statutes of Indiana of 1894, provides for the appointment of a board of examiners consisting of five members, three of whom are to be chosen by the Indiana State Dental Association. This section, it was contended, in *Ferner vs. State*, was unconstitutional, as in violation of a clause in the State constitution forbidding the granting of privileges which shall not, upon the same terms, equally belong to all citizens. It was argued that by said section a special privilege was given to the Indiana State Dental Association of naming members of the Board of Examiners, and prescribing the standard of qualification. But the supreme court of Indiana holds, Oct. 12, 1898, that said section 5596 does not contravene the constitution. It says that it is not necessary that members of the Association shall be appointed upon the Board. And it looks at the power to appoint as in the nature of a duty, rather than a privilege, insisting that it may not be said to be a special privilege any more than that conferred upon circuit judges to appoint city

commissioners or a drainage commissioner, or that the governor, the president of the State University, and superintendents of common schools shall be members of the State Board of Education, or in many other instances where non-judicial functions are imposed upon judicial officers, or non-executive functions are cast upon the executive, or where men, by reason of their learning, are designated to perform a service to the public. Taking up the suggestion that the act in question does not afford due process of law, in that it fails to extend the right of appeal from decisions by the board, the court says that it may be seriously doubted if one who does not seek a decision of the Board may complain that he could not appeal from its action, and that it may be suggested, also, that the general rule is that appeals are recognized as allowable from judicial decisions only, and that boards of the character of that in question do not render judicial decisions. Moreover, the party here charged with unlawfully practicing dentistry, and convicted, objected that the evidence did not support the verdict that he engaged in the practice of dentistry. It showed that he leased and occupied rooms for several months for the declared purpose of practicing dentistry; that he had done dental work for three or more persons; that at times he engaged in filling teeth, and at other times did dental work at the bench. This, the supreme court regards as sufficient to require the inference that he engaged in the practice. It also thinks it quite clear that it is made a crime to practice dentistry "without being registered," registry, within the purpose of the law, relating to the permanent authority to practice dentistry, and that the temporary permit issued by any member of the Board of Examiners is a protection only until the Board shall meet to make the registry.

Our Cuban Exchange.—We are glad to welcome once more the *Revista de la Medicina y Cirurgia de la Habana*, which we have missed from our mail since last spring. The *Revista* is a fortnightly journal, but the numbers we have just received, Nos. 7 and 8, bear date of April 10 and October 10. They contain no reference to any events in the interim, but calmly resume their scientific communications with the description of a case of putrefied placenta with a living child.

Artificial Assistants.—The burlesque number of the *Munich Med. Woch.*, issued on the sixty-fifth anniversary of the local medical society, is an exact reproduction of the regular make-up, but sparkling with fun in every line. The rear outer cover is a display ad. of artificial assistants for surgeons, etc. "The disadvantages of the living assistants hitherto in use are familiar to all. They assist, but have too many annoying 'secondary effects.' Some are unable to keep their mouth shut, some have 'exaggerated reflex excitability,' some have opinions that differ from those of their chief and criticize him, some leave matches around and the gas burning, some shock spectators by their lack of gentleness. These drawbacks are all entirely obviated with our new patent glass and iron assistants, transparent, sterilizable, to connect with either electric or steam power. They are supplied in two grades, smooth or rough finish, for private practice or general hospital work. They are adjusted for only one or two specialties each, but extra specialty appliances can be screwed on as desired. Assistants for surgeons: Say 'sponge' and 'gauze': Style A. Wipes 10 times a minute, 1200 Marks; B. Wipes 20 times a minute, 1300 M.; C. No hinge in back, 1100 M.; D. Without buttocks (an important improvement, allowing spectators complete oversight of the operation) 2000 M. For internal medicine: Do percussion, and find albumin in urine: A. Once an hour, 100 M.; B. Three times an hour, 150 M.; C. Stain bacilli, 200 M. For obstetrics and gynecology: Style A. Automatically perform vaginofixation on every uterus, 10 M.; B. Ditto vesicofixation (new), 20 M.; C. Antefixation according to indications, 200 M.; D. Abhor all therapeutic treat-

ment of retroflexion, 600 M., etc." The leading article is a report of successful experimentation to secure asexual propagation of the human species by fission, accomplished by administering an extract, Tolstoidin, thus named from the idea having been suggested by the disapproval of the sexual methods expressed in Tolstoi's "Kreutzer Sonata."

Contributions to the Army Medical Museum.—The officer in charge of the Army Medical Museum has invited attention to the possibility of enriching the Museum by contributions from general hospitals and hospital ships, and the Surgeon-General of the Army has published the communication in the form of a circular from his office. The contributions referred to in paragraph 147, "Manual of the Medical Department," are rare pathologic specimens from animals, including monstrosities; typic crania of Indian tribes, specimens of their arms, dress, implements, rare articles of their diet, medicines, etc., and specimens of poisonous insects and reptiles and of their effects on animals. The communication is as follows: The contributions to this Museum from the active theater of the recent war with Spain and from the extensive field of subsidiary operations, have been so few and unimportant that it seems desirable to renew the attention of medical officers to this important subject. The hurry and peculiar military conditions of the Santiago campaign, and amount of work imposed upon the medical officers in our large camps of instruction would naturally obscure the more remote interests of the Museum; but from our large general hospitals and hospital ships and the more deliberate methods of our forces of occupation may well be demanded a return to the systematic collection of specimens illustrating the bone and tissue injuries produced by modern firearms and explosives, and a careful preservation of such illustrations of disease as may be obtained upon cadaveric examination. As it will be necessary to add a guide to the preservation of specimens, the following suggestions have been prepared: Soft tissues are preferably placed in a 20 per cent. solution of commercial formaldehyde (or formalin), the specimen being completely covered by the solution. The fluid on very soft tissue, or large masses of tissue, such as the liver, spleen, etc., should be changed after two or three days. When formalin is not obtainable, commercial alcohol may be used. Bones and joints, after having been roughly cleaned, may be simply wrapped in a cloth wet with the preservative solution, and then again wrapped in oiled paper or silk. Since glass and earthenware vessels are liable to be broken in transit, with escape of their fluid contents and damage to the specimens, the use of tin vessels is recommended, the covers to be tightly soldered on. Whatever vessel is used should be packed in sawdust, excelsior packing, stiff paper, or equivalent substitute, in a wooden box. Small dry specimens may be sent by mail; and wet specimens also, if enclosed in the boxes which have been approved by the Post-Office Department. Specimens should be carefully numbered, and a letter of information forwarded to the Museum when the specimen is shipped; the letter to contain the number of the specimen, a description of its nature, and if possible, its history. In addition to the contributions specified, those enumerated in paragraph 147, "Manual for the Medical Department," are especially worthy of consideration, in view of the opportunities offered in our new territory. Although paragraph 1130, A. R., provides for the transportation of all such contributions through the Quartermaster's Department, it should be known that if the importance of the object, or security demands a more prompt delivery, the package may be shipped to the Curator of the Museum by express, the charges to be paid here. The receipt of any package will be duly acknowledged, and credit given for the contribution.

Expensive Charity.—The *Bulletin Méd.* of Paris relates that a woman recently applied to the free dispensary at the "Quinze

Vingt" for treatment, but had the thoughtfulness to remove a pair of diamond ear-rings from her ears and put them in her pocket before entering the room. When she received her consultation ticket she found that the solitaires, worth 4000 francs, had disappeared from her pocket, and in spite of a large reward offered were never recovered.

Societies.

The following recent meetings are noted :

Illinois.—Chicago Society of Internal Medicine, November 22; Fox River Valley Medical Society, Aurora, November 15.
Indiana.—Allen County Medical Society, Fort Wayne, November 15.

Iowa.—Eastern Iowa District Medical Association, Keokuk, November 17.

Kansas.—Topeka Academy of Medicine, November 14.

Michigan.—Saginaw County Medical Association, Saginaw, November 11.

Missouri.—St. Louis Academy of Medical and Surgical Sciences, November 22; St. Louis Medical Society of Missouri, November 19.

New York.—Binghamton Academy of Medicine, November 15; Kings County Medical Society, New York City, November 10.

Ohio.—Muskingum County Medical Society, Zanesville, November 10.

Tennessee.—Maury County Medical Society, Columbia, November 15.

Philadelphia.

REQUESTS TO CHARITY.—Through the death of William W. Whitehead, a bequest of \$500 has been received by the Samaritan Hospital of this city, and through the death of Abraham McGarry, \$1000 to St. Joseph's Hospital.

LAST HOSPITAL TRAIN.—Recently the last hospital train was dispatched to Camp Meade by the relief commission, returning with sixty patients, who were distributed to the Woman's, St. Joseph's and St. Agnes Hospitals.

DR. JOHN BLAIR GIBBS.—Many have been the honors conferred upon this distinguished physician, who lost his life upon Cuban soil, but the latest one is that of his academic alma mater, Rutgers College, which recently unveiled a memorial tablet in Kirkpatrick Chapel at that institution.

MORTALITY STATISTICS.—During the week just closed there have been reported to the Bureau of Health a total of 414 deaths, an increase of 17 over last week and of 75 over the corresponding week of last year. Of the total number of deaths, 116 occurred in children under the age of 5 years.

PERSONAL MENTION.—Among the Pennsylvania soldiers being mustered out of service may be mentioned Battery A of Philadelphia. In order to establish the condition of the men upon their discharge, competent examiners have been commissioned to make a thorough physical examination of the men. The names of the physicians who are conducting this work are: C. F. M. Leidy, Joseph Shellisey, Ward Brinton and Walter Roberts.

DEATH AMONG SOLDIERS.—Within the past two weeks two deaths from typhoid fever have occurred among soldiers at the hospitals. The first death was that of John M. Warner, Company M, Fourth Pennsylvania, who contracted the disease in Porto Rico and was subsequently brought to this city on the hospital ship *Relief*. The second case was that of Samuel Pemberton of Company A, First Delaware, who contracted typhoid fever in Camp Meade and was brought here October 22.

LECTURES ON X-RAY.—Dr. Charles I. Leonard is giving a series of lectures at the University Hospital on the subject of skiagraphy, describing the method and apparatus used, as well as the theory on which the subject is based. In the lecture of Saturday it was proposed to describe the method of taking the photographs of different organs and different parts of the body, as well as to draw conclusions from the study of the plates, so that a diagnosis could be made of diseased conditions.

QUARANTINE AGAINST HYDROPHOBIA.—Whether it be true or not that hydrophobia is an acute infectious, contagious or inoculable disease, the State Board of Health has seen fit to quarantine against all dogs in a village near the northern border of the State, for a period of ninety days. This action has been taken on account of an epidemic of hydrophobia there for some time among cattle, horses and swine.

IMPROVEMENTS AT GERMANTOWN HOSPITAL.—This busy hospital will soon have proper accommodations for an isolation ward for the treatment of cases who can not be cared for in the other departments. The addition is to contain three rooms for patients, one room for nurses, and one for a sick-diet kitchen. The addition is one story in height, with basement, built of brick and tile and will cost several thousand dollars. The ward is the gift of Mr. Stephen Green, and was given as a memorial to a member of his family. The building will have all the latest improvements.

WAR INVESTIGATING COMMITTEE.—It is reported that this committee will visit Philadelphia within the next ten days. Just the object of the visit is not fully known, but it is thought to be in connection with the offices of deputy quartermasters and office of Chief Medical Inspector Peyton. Several are mentioned who, it is thought, will be summoned to go before the Board and testify as to what they have witnessed during the course of the war. The officers of the different departments feel confident that no exception will be taken to the method in which the business of these departments have been conducted. So far no complaint has been made against either official in charge of the officers stationed at this place.

RELIEF TO SICK SOLDIERS.—The Hospital Committee of the Woman's Sanitary League, which has been associated in the relief of soldiers at the Polyclinic, Medico-Chirurgical, St. Agnes, Jefferson, University and Women's Hospitals, recently held another meeting and elected officers. The Executive Board consists of five principal officers, with chairmen of standing committees and other members. Committees are also appointed on education, hospitals, legislation, sanitary science and municipal questions. The Hospital Committee was instrumental in furnishing money, supplies and delicacies for the sick during the summer months just closed.

DR. CHARLES H. FRAZIER.—Owing to the resignation of Dr. J. William White, from the surgical staff of Blockley, some weeks ago, in order to assume charge of the clinical work at the University of Pennsylvania, the Board of Charities and Corrections, at a recent meeting elected Dr. Charles Harrison Frazier as successor to Dr. White. Dr. Frazier is a graduate of the University of Pennsylvania, 1889 (College) and 1892 (Medical). He was resident physician to the University and Episcopal Hospitals and subsequently resumed his studies in the University of Berlin and is a member of the surgical staff of Howard Hospital and assistant-surgeon at the University Hospital and to the Out-patient Department of the Episcopal Hospital, and also a member of the editorial staff of the *Philadelphia Medical Journal*.

MARINE SOLDIERS.—During jubilee week in Philadelphia, there were a number of sick soldiers removed from several vessels at anchor in the harbor, and transferred to the Marine Hospital. Eleven of them were removed from the *Texas*, ten from the *Topeka*, one from the *Minneapolis* and one from the *Richmond*. In many instances the disease subsequently proved to be typhoid fever. It is reported that it is the opinion of the medical officers stationed on the *Texas*, that, as there has been no means of contact with infected men, the disease in the present instances has resulted from bad food or impure water on board the vessel. In the Marine Hospital there are at present eighty-eight cases, a great increase over the usual average. This state of affairs has doubtless been brought about by the fact that there are more vessels here at present than have been in Philadelphia for many years.

NATIONAL RELIEF COMMISSION.—Mr. George C. Thomas, treasurer of the National Relief Commission, makes the following statement through the banking firm of Drexel & Company: Cash previously acknowledged, \$78,405.40; various donations, \$68.17; value of supplies received to date, \$40,345.00; grand total, cash and supplies, \$118,808.57. From this report it is observed that the total amount of money is increased but little from week to week, while the work with which it is engaged necessarily goes on, from the fact that sick soldiers are transferred from army corps by money provided by the Commission. Up to the present time most of the sick soldiers have been brought to Philadelphia, but it is thought that hereafter the majority will be taken to Baltimore and other cities. The outcome of the trip of President John H. Converse and Secretary French of the National Commission, to Washington, where they went to confer with the War Department, regarding the future action to be taken by the Commission, has not been made public, but it is believed that the visit was not altogether encouraging to the Commission. Having carried on work which it was thought should have been done by the Government, the Commission had a right to expect support from that source, but up to the present time it may be said that the prospects are discouraging.

Dr. BENJAMIN LEE.—At the forty-first regular meeting of the State Board of Health, recently held, the secretary, Dr. Benjamin Lee of Philadelphia, made his report, dealing largely with cases of communicable diseases that have occurred in various portions of the State, including inspections made and sources of pollution.

A CASE OF SUPPOSED LEPROSY.—Last week a Russian sailor was taken to the Municipal Hospital, thought to be suffering from leprosy. It is stated that the man gives his nativity as Arensburg, in the Island of Oesel in the Baltic Sea, where the disease is quite prevalent.

HOSPITALS WILL BE REIMBURSED.—It is reported that it is the intention of the Government to reimburse all hospitals for the expense incurred in caring for the soldiers brought to those institutions. It is a source of some gratification also to state that while the hospitals of Philadelphia were first to volunteer their facilities to the Government that in no instance (*Press*) has a bill been sent in, as has been done by hospitals of two near by cities. The Government now volunteers to pay to all such hospitals sixty cents a day for each soldier so treated, and, furthermore, to reimburse all institutions who have been instrumental in sending out hospital trains to the different army camps.

REDUKE FOR PHYSICIANS.—A complaint has been lodged against the profession by a resident of Germantown, who states that cases of diphtheria are not properly reported and thereby the disease becomes more common.

POISONING BY CASTOR BEANS.—Recently, while playing near a vacant lot, three children ate of castor beans which had been thoughtlessly thrown from a neighbor's garden. Soon afterward all these children became violently ill, but in one case death resulted from acute nephritis. While the other two children were also suffering from the same disease it appears milder, and hopes are entertained for their recovery. The cases have been reported to the Board of Health by the coroner's jury, who thought the owner of the lot should be thoroughly censured for not complying with the city ordinance requiring that all vacant lots be enclosed.

PROCEEDS OF CHARITY BALL.—The hospitals which have already applied for proceeds of Charity ball to be given soon are: Children's department of the University Hospital, Free Hospital for Consumptives, Samaritan Hospital, St. Christopher's Hospital, St. Timothy's Hospital, Children's Hospital.

LECTURE ON SICK DIET.—At the Food Exposition now being held in this city, Mrs. Rorer, who has obtained a national reputation in the art of cooking, gave a lecture on Doctor's day, on

the preparation of foods for the sick. The lecture was largely devoted to the albuminoids, and formulæ were given for such articles of diet as albuminized whey, frozen junket, chicken, panada, and beef paste. The lecturer also dwelt largely upon the subject of infant feeding, especially regarding milk, taking the view commonly held by the medical profession, and the subject in this way may be presented so that much good may arise from the lecture.

DIPHTHERIA AGAIN RAMPANT.—Diphtheria has spread rapidly in the northern section of the city, and for the week just closed four deaths from the disease have occurred in that section. The disease exists in both public and parochial schools, and the principals of those institutions state that owing to the prevalence of the disease there are many absentees, and as no one has been detailed to look after these students it is not known whether they remain away for fear of contracting it or whether they have already been affected.

DR. WILLIAM ASHHURST, who has for several years been practicing medicine in Mexico, has returned to the city and has established offices at his father's residence, 2000 West DeLancey Place.

DR. AND MRS. S. WEIR MITCHELL will leave shortly for Europe, and subsequently, Egypt, where they go for the benefit of the health of Mrs. Mitchell, who has been slowly convalescing from the serious illness of last winter.

DISLOCATION OF ENSIFORM CARTILAGE.—A man weighing 200 pounds has been admitted to St. Mary's Hospital for a dislocation of the ensiform cartilage. The patient is an employe of a large mill, and it is supposed that the injury was received while performing his usual duties in lifting several heavy gates about the premises.

Washington.

HEALTH OF THE DISTRICT.—The report of the health officer for the week ended November 12, shows the total number of deaths to have been 98: 69 white, and 29 colored. The principal causes of death were: Nervous diseases 11, circulatory 7, genito-urinary 6, consumption 15. There were 5 fatal cases of typhoid fever, 4 of diphtheria, 1 each from whooping cough and scarlet fever. At the close of the week there were 130 cases of diphtheria and 120 of scarlet fever. There were 124 births, of which 61 were white and 63 colored.

CENTRAL DISPENSARY AND EMERGENCY HOSPITAL.—At the meeting of the Hospital Board, November 11, the report of the attending staff showed a steady increase in the work of the hospital. The board has decided to make extensive improvements in the building. The operating and the emergency rooms are to be remodeled and new tile floors and steel ceilings placed throughout the building. The Ladies' Auxiliary Board has offered to appropriate \$800 to assist in the improvements.

CONTAGIOUS HOSPITAL FUND.—At the special meeting recently held by the Daisy Chain Hospital Promoters, it was decided to donate the \$12,000 to the Garfield Memorial Hospital to assist in building the contagious disease hospital, now in course of erection. The funds are available immediately.

FOR REMOVAL OF WEEDS.—Health Officer Woodward has prepared a bill enforcing the removal of weeds from building lots in the district. The Bill provides that whenever there are weeds four or more inches in height within the district, the owner or occupant of the premises shall remove the same after seven days' notice. A penalty of \$10 fine is provided.

PURE FOOD LAW ENFORCED.—Three grocers were recently fined \$15 each for violating the Pure Food Law. It was shown in court that they exposed for sale and sold a commodity called lard, which, after examination by the district chemist, proved to contain no lard whatever, and which was a mixture of beef tallow and cottonseed oil. The health department is rigidly enforcing this law and, as a result, many of the adulterated foods are disappearing from the shops.

WILL OF DR. HARRISON.—The will of the late Dr. George

Byrd Harrison has been filed for probate with the registrar of wills. The instrument was made in 1883, and bequeaths all his immense estate to his wife.

ANOTHER SURGEON SUE.—One Forest has recently entered suit against Dr. Thomas P. Mallon of the Providence Hospital, seeking to recover damages in the sum of \$10,000. The usual declaration is set forth, "incompetent doctor, short leg, subsequent pain and suffering, and a need of money to soothe the woe." This is the second suit of its kind recently entered in the District, and the doctors may expect an epidemic of such suits. It is rumored that a son who was born with a short leg is about to enter a suit for damages against his mother.

MILITARY SURGEONS ASSIGNED.—Major John W. Bayne, brigade-surgeon, U. S. V., has been ordered to Washington and placed in charge of all sick men of the Army arriving here. Acting Asst.-Surgeons Chas. G. Marbery and George D. Morris have been ordered to return from Chickamauga and Porto Rico, respectively, and report in person to the Surgeon-General.

Louisville.

KENTUCKY UNIVERSITY.—The announcement of the Medical Department of Kentucky University has just been issued, with the following faculty: T. C. Evans, dean, professor of ophthalmology, otology and laryngology; Henry E. Tuley, secretary, professor of principles and practice of medicine and diseases of children; Leon L. Solomon, professor of materia medica and therapeutics and of pathology; Carl Weidner, professor of physiology and histology; W. Ed. Grant, professor of chemistry and cutaneous and genito-urinary diseases; J. Garland Sherrill, professor of surgery; Henry L. Stone, A.M., professor of medical jurisprudence; and the following clinical professors: T. E. Evans, ophthalmology, otology and laryngology; Henry E. Tuley, diseases of children; Leon L. Solomon, medicine; Carl Weidner, medicine and diseases of the chest; Henry R. Koshler, cutaneous and genito-urinary diseases; Louis Frank, gynecology and abdominal surgery; J. Garland Sherrill, surgery. The following are of the corps of instructors and laboratory directors: Sam. Holloway, surgery; Geo. C. Leachman, anatomy; John E. Hays, histology and bacteriology; Louis Rominger, histology. Kentucky University is the result of the coalition of Bacon College and Transylvania University in 1799, since which time it has been known as Kentucky University. The University comprises four colleges, each under the government of its own faculty, and an academy or preparatory department, in charge of a principal and assistants. The four departments are located at Lexington, Ky., but the curators of the University, desiring to establish the Medical Department, have chosen Louisville for the location of it. The College has adopted the requirements of the Association of American Medical Colleges and the teaching will be upon the broadest and most enlightened line of medical teaching. It has obtained quarters in the building formerly occupied by the Louisville College of Pharmacy and has fitted up elaborate laboratories and clinics-rooms, there being already adequate lecture-rooms.

CONTAGIOUS DISEASES.—A change has been made in the law governing the reporting of contagious diseases, to include typhoid fever, consumption and whooping cough. The list already includes scarlet fever, diphtheria, smallpox and cholera.

Detroit.

WAYNE COUNTY MEDICAL SOCIETY.—At the regular meeting held November 17, Dr. J. A. Weitz read a paper on "Infantile Paralysis." He said that the prophylaxis and management of infantile paralysis were not given the attention that they should have by the medical profession generally. The belief was too common that it is beyond our power to prevent in any measure the occurrence of the evil or mitigate the results. He divided the cerebral palsies of infancy into three classes: fetal, natal and post-natal. The fetal cases, he said, are evi-

dently the result of prenatal influence, due mainly to errors in development, with occasionally a case dependent upon traumatism or infection in utero. As to post-natal cases, all evidences point to vascular obstruction as the lesion, whether thrombosis or embolism, is not definite. Toxemia in childhood often produces convulsions and temporary loss of power, but these are not included in the class of post-natal infantile paralysis or hemiplegia. Convulsions in young children, from apparently trivial causes, are so frequent, without serious result, that the profession are not sufficiently awake to the grave possibilities surrounding a case of this kind. We are thus frequently taken by surprise. In the class of cases mentioned as natal palsies the pathology is quite definitely settled, although investigations have been comparatively recent. The cause is probably always meningeal hemorrhage. In the prenatal cases our duty consists largely in the proper care and management of the prospective mother. In post-natal cases we have a similar office to perform in the management of the children among our clients, with the additional duty of directing the training of the residue of brain after an injury of this kind, besides conducting the case through the attack of acute symptoms. As the cases of cerebral hemorrhage are nearly always due to traumatism at the time of labor, we have a more active duty to perform in the matter of prophylaxis and in the active interference for the relief of the lesion. The cases are always due to difficult labor, where instrumental delivery is called for, so it behooves the physician to make vigorous efforts to prevent the condition which would give rise to a difficult labor. Where the lesion has occurred surgical interference should be tried for the relief of the condition.

CHANGE OF ADDRESS.

Anderson, J. A., from 8042 Edwards Av. to 151 Cheltenham Pl., Chicago.
Blue, W. R., from 1807 4th St., to 2205 3d St., Louisville, Ky.
Catlin, G. E., from Lake Geneva to L. B. 532 Marshfield, Wis.
Cummings, Wm., from 5th and E Sts. to 820 5th St., San Diego, Cal.
Davison, J. A., from Eldorado to 715 Washington St., Dayton, Ohio.

ORIGINAL ARTICLES.

PRINCIPLES OF THE DIETETIC TREATMENT OF DIABETES MELLITUS.

Read before the Chicago Society of Internal Medicine, Nov. 22, 1898.

BY C. W. PURDY, M.D., LL.D.

CHICAGO, ILL.

I have been greatly honored by this society in an invitation to present before its members some of my views upon diabetes. While such a task is by no means an unpleasant one, in view of the great intrinsic interest of the subject, the importance of the class of cases in clinical practice and, lastly, the familiarity of the picture to my mind, in consequence of having with considerable care and thought gone over this field with special interest for a number of years. I must, however, confess some hesitation in the undertaking, since very divergent views have been held upon the subject by so many eminent observers, not only as to the etiology and pathology of the disease, but also as regards its proper management. In addition to this the literature of the disease—which is prodigious in volume—is yet so inharmonious and even contradictory, as a whole, that it is exceedingly difficult to glean from it any very uniform or systematic basis of knowledge of the true nature or pathology of the disease. But while our knowledge of the nature and pathology of diabetes at present rests very largely upon theory and speculation, experience has taught us much that is valuable in the management of the disease, and therefore, it has seemed to me that the present discussion might prove most valuable and useful if confined largely within the limits of management. I have consequently chosen as the subject for present consideration the principles of the dietetic management of the disease, to which has been added a request that I make some special reference to the disease as it appears in the aged.

The dietetic management of diabetes has been a somewhat stereotyped matter for very nearly a hundred years, the old diet lists and forms having been perpetuated both in clinics and in text-books with comparatively few alterations since the days of John Rollo. This is the more regrettable in view of the fact that very decided advances have been made upon this subject within a comparatively recent period, so that our power of controlling the disease and of conserving the lives of these patients has been very distinctly advanced.

As regards the disease in the aged. So far as my own individual experience and observations are concerned, I have come to look upon diabetes after middle life as one of the most manageable diseases with which the physician has to do, if he only has entire control of the patient. So strong, indeed, has become my conviction of this fact as it appears to me, that I am in the habit of meeting the issue squarely with my

patients in the assurance that if they fall victims to the disease it will be the result either of their own or my neglect. I refer here especially to primary cases in people over 50 years of age, who have not already been neglected to the extent that the disease has made serious inroads upon the strength, and especially upon the body weight, of the patient. On the other hand, the compact between the physician and patient must be of the most solemn and vigilant order if the concerted assault upon the disease is to prove successful, because no other disease demands more detailed observation and closer watchfulness in all details of management, and the reasons therefor will be considered subsequently.

The diet of diabetic patients should be so ordered as to maintain and, if possible, increase the body weight and strength of the patient, as these are the first to be undermined by the disease. Now, in order to compass these primary objects, a systematic series of frequently recorded observations must be made of the quantity and quality of the food actually ingested; of the quantity and quality of the waste excreted, especially by the kidneys; and of the actual body weight. By this means only is it possible to detect those disturbances of metabolism caused by the disease and to refer directly to their cause. We shall be in a position still better to estimate these if we first take a brief survey of the relative and actual values of the various food products at our command. By comparing these with the known physiologic requirements in health, we shall be enabled the most readily to supply those deficiencies caused by the disease, and thus maintain that equilibrium of metabolism upon which all successful management depends.

In physiologic observations it has become the custom to adopt Rubner's suggestion of measuring body energy or force, which results from oxidation changes in the economy, by the unit value of the calorie—or the heat unit. We understand by the word "calorie" the amount of heat necessary to raise one kilogram of water one degree Centigrade. It has been ascertained after careful and repeated investigations that all our food products, through their consumption in the body, produce definite amounts of heat, or the equivalent of this measure in the form of force. By grouping together the various food products in their several chemic groups we shall be able readily to glance at the calorie value of each, and thereby adjust our diet list so as to cover the actual requirements of the economy. For example, it has been found that one gram of albumin, through its conversion into urea, water and carbonic acid, yields approximately four calories of heat or force; that one gram of carbohydrate, through its conversion into water and carbonic acid, yields approximately the same, i. e., four calories; that one gram of fat, by its conversion into water and carbonic acid, yields a little over nine calories; and that one gram of alcohol yields about

seven calories. With these data before us it is easy enough to establish a diet-ration that will readily maintain the equilibrium of metabolism in a healthy individual, since all we have to do is to furnish him food in quantity and quality such as will represent 2500 to 3000 calories. Thus from 100 to 120 grams of albumin, 55 to 70 grams of fat and from 400 to 500 grams of carbohydrate would cover the requirements, and these are about the average proportions of each naturally used in health.

In the case of the diabetic patient the problem is not so simple, because the carbohydrate foods in such cases are rendered more or less inefficient for the reason that they are more or less—indeed, sometimes totally—excreted in the urine as unused or waste material. We can very readily perceive what a serious obstacle is placed in the way of supplying the normal amount of nutritive material by the withdrawal of the whole or even a considerable proportion of the carbohydrate group, constituting as it does normally at least 60 per cent. by weight of the whole daily ration. Fortunately, however, in many cases of diabetes—in fact, in most cases after middle life—a very considerable capacity of utilizing carbohydrates remains. In such cases we may, therefore, give more or less carbohydrates, and the deficiency in heat or force units remaining may usually be made good by increasing the proteids. I have frequently in such cases been able to give from four to six ounces of ordinary table bread daily without causing sugar to appear in the urine, and this represents a calorie value of from 400 to 500 units.

As previously indicated, there exists among diabetic patients the greatest differences in individual capacity for utilizing the carbohydrates. Some can take and utilize comparatively large amounts, as has just been shown; others very much smaller amounts, while a few can not take carbohydrates in the smallest quantity without their immediate escape by the urine in the form of sugar. Not only this, but also very wide oscillations of the tolerance for carbohydrates occur in the same case at different, and sometimes, very briefly separated periods. We are not always able to fix upon the precise cause of these oscillations, because we are not entirely familiar with all the influences which lead to them, but they furnish us one of the strongest reasons for constant vigilance over the balance of metabolism. Again, some cases may ingest 200 grams of carbohydrate food and lose 45 or 50 grams by the urine, leaving available for the system 150 grams, nearly 450 units. In such case it is clearly good policy to allow a moderate proportion of carbohydrate food, both for its value as a strengthening and building material and for the variety it offers the patient in his daily ration.

Unfortunately, in some cases of diabetes, comprising chiefly spare subjects in the aged, and at some time all young subjects of the disease, carbohydrates can not be used without their total escape in the urine. In such cases the use of carbohydrate foods in any considerable quantity is distinctly injurious to the patient in more ways than one. In the first place, if these cases are put upon carbohydrates, in time they develop a decidedly decreased capacity for assimilating starch and sugar in all forms, because the cells concerned in sugar consumption are functionally weak and impaired, and their overwork leads with certainty to total impairment of function. In addition to this, the increased percentage of sugar in

the circulation—hyperglycemia—which always occurs under such circumstances, can not but be responsible for at least some of the many secondary complications of the disease; and in the aged especially, I might mention the damage so often resulting to the cardiac muscle, which so suddenly terminates the lives of so many aged diabetics. Again, if carbohydrates be liberally supplied in severe cases, they are not only of little or no use to the patient, but they take the place of other foods which would be valuable in sustaining nutrition. The picture must be familiar to all of you, to see diabetics who tell you that they can not get enough to eat, and are weak and spare. They eat and stuff themselves, yet grow daily weaker and more emaciated because their food largely escapes as waste unutilized by the organism. While the stomach is overloaded the tissues are starved. We may, therefore, safely accept the proposition that the use of carbohydrate foods in the severe grades of diabetes surely proves injurious if, indeed, not dangerous, and hence we must look to other sources to supply the deficiency made necessary by the withdrawal of this class of foods.

If we turn to the proteid group with the view of making this the exclusive source of supply, we are met by the serious fact that it is an absolute impossibility to introduce enough nutritive value in proteid to compensate the daily loss of material and force in the economy. Noorden points out that "1000 grams of meat and six eggs furnish at most but 1500 calories; a deficit of at least 1000 calories remains with its injurious consequences," if we attempt to diet these cases exclusively on proteids, and yet an exclusive meat diet has among us enthusiastic advocates. It is clear, however, that we can only increase the ratio of proteids with safety to certain limits, after which we must look to other sources to supply the deficiency resulting from withdrawal of the carbohydrates. It is precisely in this direction that the greatest advance has been made in the dietetic treatment of diabetes in recent times. By the substitution largely of fat we obtain a closely allied group of foods, chemically speaking, which represent a value in units nearly three times greater, and eminently suitable for our purposes. The French school was the first to recognize the value of the use of fats in these cases, and this principle has been incorporated in the French practice for a considerable time past. More recently it has been adopted in Germany and with much success. It has already been shown that the calorie value of fats is over 9 units per gram, while that of proteid and carbohydrates is only 4 units. It so happens in diabetes, for the most part, that there is a remarkable tolerance for fats; indeed, many of these patients have a special liking for fatty foods. In moderate grades of diabetes no difficulty will be encountered in substituting fats for a partial withdrawal of carbohydrates. These cases will, under such management, lose their glycosuria, gain in weight and strength, and progress most satisfactorily. The only question in this connection calling for serious consideration is that of the entire substitution of proteid and fats for carbohydrates in those graver forms of the disease in which all the carbohydrates taken into the system are immediately eliminated, or still more serious when even larger amounts of carbohydrates are excreted than are taken into the organism, as is sometimes the case. The argument that diabetic patients will not assimilate large quantities of fats has been repeatedly disproved, both experimentally and in actual practice.

so that the converse of this may be accepted as a rule to which there are few exceptions. Indeed, as much as 150 grams of fat have been given—representing 1350 calories—and with results most satisfactory. It has been demonstrated through Weintraud's experiments and observations upon metabolism, that the entire substitution of fats for carbohydrates effectually prevents the wasting of the body albumin and conserves the weight and strength of the patient.

There has existed a somewhat prevalent idea—although an entirely theoretic one—that large amounts of flesh foods predispose to diabetic coma. Now what little we think we know of the nature and cause of diabetic coma at present rests upon pure theory. In actual practice we certainly find that diabetic coma usually arises in those cases attended by a high percentage of sugar in the urine, and moreover, usually at the period or soon after the sugar excretion reaches its maximum. Furthermore, we are taught to believe and, I think, properly so, that the lower we are able to reduce the sugar percentage in the urine, the further shall we remove the patient from the danger of the appearance of coma. It should be borne in mind that an exclusive proteid diet is not here advocated, but rather the discussion is in favor of a proteid and fat diet in certain cases. I can not perhaps more tersely express the advanced views upon this question in conclusion than in the words of Noorden, to whom we owe so much for his classic digest of our knowledge on the subject. He says: "From what I have been able to glean from the literature, from what I myself have seen, and from what has been related to me by other judicious partisans of the fat-and-flesh diet, it appears to me that the dread of coma so produced is wholly unfounded. I believe, therefore, that for every really grave case of diabetic glycosuria, the fat-and-flesh diet to the exclusion of carbohydrates is to be regarded as the ideal regimen, against which no serious objection can be raised."

It remains in this connection to speak of the place that alcohol should occupy in the regimen of the diabetic, or if its use be advisable at all, and this question should receive careful and sincere consideration. We must, in the first place, keep in mind the well-known dangers of the use of alcohol to the nervous system, especially when employed in considerable quantities; and, moreover, we must not lose sight of the fact that the majority of diabetic patients are decidedly neurotic. So thoroughly has this been recognized, that many observers have claimed for the disease a nervous origin. Without admitting the latter as true, but recognizing the undoubted neurotic tendencies of these patients, it is clear that the use of alcohol has its dangers, especially if allowed in any large amounts, and therefore, if admissible it must be with due caution and only within strictly moderate limits. On the other hand, we can not ignore the fact previously alluded to, viz., that alcohol is an agent of considerable value as a food, possessing, indeed, about 7 units per gram, or nearly double that of proteid and carbohydrates. Now, in the more serious cases, where the range of diet is so limited, any change whatever comes as a decided relief both to the palate and stomach. The sense of relief to a full stomach by the post-prandial swallow of cognac is well known. We are also aware of the stimulus to the appetite and digestion afforded by the use of a glass or two of good wine, especially when served with the meat course, and particularly is this the case

if much fat is served. It is precisely here that alcohol may be made valuable to diabetic patients as an adjunct food. By serving alcohol in proper quantity with the fatty foods, it enables the patient more readily to increase his fat ration, while at the same time, by furnishing in itself considerable potential force—about 70 calories to the average drink of spirits as whisky—it reduces the actual amount of fat required by an equal number of units. This is important where so much fat is to be consumed, but especially so in the more limited class of cases in which fats are not very well tolerated. Noorden lays down the rule that the average daily allowance of alcohol in ordinary cases of diabetes should not exceed 60 grams. This in itself represents a value of 420 units. This quantity of alcohol (60 grams) is contained in about 4 ounces of whisky; in brandy it would be about 3½ ounces; in white table wine, as Moselle, it would be 30 ounces; in medium grades of claret it would be 23 ounces; in good Burgundy it would be 24 ounces. In prescribing alcoholics each case should be studied upon its individual merits. In some cases the amount should be more moderate than above indicated, especially in those who are unaccustomed to its use, in very young subjects, and in the very pronouncedly neurotic. On the other hand, exceptional cases are met with in which 60 grams of alcohol may with benefit be considerably exceeded, notably in those long accustomed to its use.

Having now somewhat broadly reviewed the essential principles upon which the dietetic treatment of diabetes mellitus should rest; I shall, in conclusion, briefly outline what seems to me the most desirable method of their application in practice. In beginning the treatment it is generally conceded that a gradual enforcement of dietary restriction is safer than an abrupt change from a liberal to a strict diet. Aside from the more serious accidents—such as coma—which some authors fear from abrupt changes, we shall certainly meet with pronounced digestive disorders if we change a liberal mixed regimen for one containing, say 650 grams of meat per day. I usually, therefore, in the beginning furnish the patient the following list of articles allowed:

All meats, including beef, mutton, veal, ham, bacon, poultry and game of all kinds—roasted, boiled, potted, smoked or preserved in any way except with sugar. Sweetbreads, kidneys, heart, tongue, tripe, brain, giblets and marrow-bones, American canned meats and meat extracts, Australian corned beef.

All kinds of fresh fish, including oysters, crabs and lobsters. Dried, cured or smoked fish, including codfish, haddock, herring, mackerel, eels, sturgeon, salmon, sardines, anchovies, shrimps, caviar, frogs and turtles. Fats, oils (animal or vegetable), butter, gelatine. Eggs, raw or cooked any way except with flour. Fresh vegetables, including spinach, lettuce, cucumbers, green string beans, asparagus, cauliflower, red and white cabbage, Brussels sprouts, soft green corn on the cob, mushrooms, onions, cress, leeks, celery, radishes, oyster plant.

Preserved vegetables, including tinned asparagus, French beans, cucumbers pickled in brine or vinegar, mixed pickles, chow chow, olives, sauerkraut, tinned French peas. Eggs, cheese, cream, butter, gelatin and all fats and oils. Spices, including salt, pepper, mustard, curry, cloves, nutmeg, parsley, capers, etc. Soups and broths, if clear and unmixed with bread crumbs, flour, barley, rice or cereals. Nuts, as almonds, walnuts, Brazil nuts and filberts. Tart, apples, strawberries, lemons, gooseberries, currants and tomatoes, in moderation, if prepared without sugar; — ounces of table bread a day.

Beverages.—Pure water, all table mineral waters, coffee and tea with or without cream, Rhine wine, Burgundy, claret.

You will observe that a blank space is reserved for bread allowance, which is usually filled in at three

ounces per day. Under the head of special instruction to the patient, directions are usually given to aim at the daily use of from 300 to 400 grams of butcher's meat, about 70 grams of fats, after which the balance of the daily ration may be filled in from the list *ad libitum*. On the third day, careful observations should be made and recorded of the following leading features: The weight of the patient as compared with that recorded three days before; the quantity of the urine; the total output of urea and sugar for the last twenty-four hours. The patient should now be kept upon practically the same lines of diet for from ten days to two weeks, observations being made and recorded of the weight, the excretion of urea and sugar every second or, at most, third day, and no specific medication whatever should be employed. Should, however, the twenty-four hours mixed urine at any time be found sugar free, the allowance of bread may be slightly increased—say to four or five ounces daily. At the end of two weeks, if the urine be not free from sugar, the above diet list is substituted by the following more strict one.

- All meats, including beef, mutton, ham, bacon, poultry and game of all kinds; roasted, broiled, smoked, potted or preserved in any way except with sugar or prohibited vegetables. Sweetbreads, kidneys, heart, gizzards, tongue, brain and marrowbones. Fresh fish of all kinds, except oysters. Dried, cured or smoked fish, including codfish, haddock, herring, mackerel, salmon, crabs, lobsters, sardines, anchovies, shrimps, eels, caviar, frogs and turtles. Fats, oils (vegetable or animal), butter.

Fresh vegetables, including spinach, lettuce, cucumbers, green string beans, asparagus, cauliflower, red and white cabbage, Brussels sprouts, mushrooms, onions, cress, leeks. Preserved vegetables, including tinned asparagus, French beans, cucumbers pickled in brine or vinegar, mixed pickles, sauerkraut, chow-chow and olives.

Spices, including pepper, salt, curry, cloves, nutmeg, English mustard, parsley, dill, capers, caraway seed, laurel. Soups and broths, if clear and unmixd with bread crumbs, flour, barley, rice or cereals. Cheese, such as Neufchatel, Gorgonzola, Stilton, Brie, and so called cream cheeses. Eggs, raw or cooked in any way without admixture of flour. Nuts, such as almonds, walnuts, Brazil nuts and filberts.

Beverages.—Pure drinking water, all table mineral waters, plain or carbonated, clear or mixed with lemon or lime juice, coffee and tea with or without cream. Rhine wine, claret, Burgundy.

It will be observed that in this list bread is omitted altogether and that carbohydrates are practically eliminated from the ration. The patient is now instructed to increase the consumption of butcher's meat to from 400 to 500 grams per day; to increase his daily fat ration to 100 grams; and to take from 20 to 40 grams of alcohol daily. The same systematic series of recorded observations should be continued every second or third day, i. e., of the weight of the patient; the quantity of the urine; the output of urea and sugar.

The majority of diabetic patients will upon this course lose their glycosuria, and begin to gain in weight and strength. In such cases the further management of the case consists in readjustment of the diet, from time to time, so as to offer the patient as much variety as possible. Thus at intervals a slight increase of carbohydrates may be tried—as an ounce of bread—in order to test the toleration point for this class of foods, but in so doing constant watch must be kept over the output of urea and the presence or absence of sugar in the urine.

In the most serious form of the disease the above lines of management will often be found inadequate to totally eliminate the sugar from the urine, and

moreover the patient still slowly loses weight. In such cases the diet must be practically restricted to flesh, fat and alcohol, with perhaps some green salad, as lettuce or cucumber. The daily ration should be made to conform approximately to the following features: 500 to 650 grams of butcher's meat, a pint of broth, 3 to 6 eggs, 130 to 140 grams of fat, and 40 to 60 grams of alcohol. This will furnish fully 2500 units, or calories, or slightly more. The large proportion of fats to be consumed presents, perhaps, the most difficult part of the dietary problem to be solved. This, however, becomes less difficult in most cases, if alcohol be served with the larger meals of fat. Then, too, if every opportunity be improved of working into the ration some form of fat that is found agreeable to the patient, the required amount is often very easily reached. With the view of facilitating this object I furnish my patients of this class the following list of highly fatty foods from which they can select the most agreeable forms for use:

Butter, fats and oils, cream, marrow-bones, bacon, fat part of ham, beef, mutton, pork; beef tongue, fat goose, mackerel, salmon, white fish, eels, sturgeon, sardines in oil, yolk of eggs, German sausage (Cervelatwurst), Cheddar cheese; also cream cheeses, as Stilton, Neufchatel, Stracchino, Gorgonzola, Brie. Green salads, as lettuce and cucumber, with French dressing.

The greatest skill in the management of these cases consists chiefly in the adjustment of the diet to the individual case; in other words, in so varying the proportions of proteid and fat as to suit the variable individual tolerance for each in each special case. We must in all cases aim to supply in fat and meat combined a food value equivalent to rather more than 2000 units. The average case will probably tolerate about 600 grams of meat and about 135 grams of fat, which covers the value in units aimed at. In the beginning it will frequently be found difficult to exceed 100 grams of fat, and in such cases we must try a proportionate increase of proteids until we can increase the toleration limit of fats. The latter is to be attained by judicious use of alcohol, up to 50 or 60 grams per day, served with the fat ration, and by experimenting with different forms of fatty foods until those are found that agree best with the case. The evidences of non-toleration, in other words, excess of proteids and fats, is marked by loss of appetite, sometimes vomiting, attacks of diarrhea, with gastro-intestinal catarrh. Upon the appearance of such symptoms the quantity of food must be reduced for a time and astringent alcoholics, such as claret or cognac, should be employed. Sometimes a very large supply of proteid food may seem to be tolerated, at least it does not cause any material disturbance of the stomach or bowels, but upon careful observation of the urine, a distinct augmentation of sugar excretion is noted as a consequence. In other words, it is not uncommon to find that in pushing the proteid ration to say 700 grams of meat per day, that considerable sugar appears in the urine and that if the meat be reduced to 500 grams per day, the sugar totally disappears from the urine. The explanation of this phenomenon is as follows: In the decomposition of the albumin molecule of the food in the process of digestion, a very considerable amount of carbohydrate is liberated therefrom—at least 35 per cent. of the albumin by weight. So long as the system is able to utilize all the carbohydrate resulting from the cleavage of the albumin ingested, the proteid ration is below the metabolic toleration point and the urine remains free from sugar; but so soon

as this is exceeded the toleration point is passed, even though the stomach may be able to retain more with comfort, and sugar appears in the urine.
